Method: Since 1977, 143 patients (72 men, median age 78, range 38–92 years) have undergone 386 TARs (median two procedures per patient, range 1–17) and have been followed up for a median of 13 (range 0–240) months.
Results: The predominant indication for TAR was comorbidity (59), locally advanced disease (33), recurrent disease after previous anterior resection (16), metastatic disease (26) and villous tumours (9). The median distance of the tumours from the anal verge was 5 cm (range 1–15 cm). Twenty-eight major complications occurred (7 per cent of procedures, 20 per cent of patients): perforation (14), bleeding requiring reoperation (5), pneumonia (4), myocardial infarction (2) and incontinence (3), resulting in six early post-operative deaths. Sixteen patients (11 per cent) required a defunctioning stoma after TAR. Eleven patients (7 per cent) underwent subsequent rectal resection (six anterior resections and five abdomino-perineal excisions). The majority of patients (64 per cent) achieved satisfactory palliation of local symptoms. Median survival varied according to the indication for TAR: metastatic disease = 4 months, recurrent carcinoma = 13 months, locally advanced disease = 17 months, comorbidity = 19 months and villous tumours = 27 months. Ten patients were followed for over 3 years with no evidence of residual or recurrent rectal disease (median follow-up 50·5, range 36–240 months).
Conclusion: Transanal resection of rectal carcinoma is a useful technique in frail patients and those with advanced local or metastatic disease who would be expected to tolerate major surgery badly.

Coloproctology 025

Short course preoperative radiotherapy: experience using an Upsalla-type regime

S. Lele*, A. Raza*, R. Kendal*, D. Radstone§, J. Bolger§, A. Shorthouse†, M.W.R. Reed†, A. Barlow, G. Jacob‡ and K.B. Hosie* **Northern General Hospital, †Hallamshire Hospital, and §Weston Park Hospital, Sheffield, Lincoln City Hospital and ‡Doncaster Royal Infirmary*

Background: A recent study using short course preoperative radiotherapy (DXT) has shown a significant reduction in local recurrence with an acceptable perioperative morbidity.
Method: We have audited our experience ($n=45$) along with the times from referral to DXT and then to surgery.
Results: The median time from referral to DXT was 36 (range 11–74) days and from DXT to surgery was 6 (3–42) days.

	Upsalla		North Trent	
	Preoperative DXT (%)	No DXT (%)	Preoperative DXT (%)	No DXT (%)
30-day mortality	2	2	6·6	5·1
Anastomotic leak rate	11	8	15·8 (3/19)	7·4
Perineal wound breakdown	20	10	24 (6/25)	<10?
No complications	56	66	55	?

Patients waiting longer than 7 days between DXT and surgery were more likely to suffer the major complications of anastomotic leak, wound sepsis or fistula formation, 6 of 13 (46 per cent) versus 6 of 32 (18·8 per cent).
Conclusion: These early results suggest that pre-operative DXT has a significant perioperative morbidity which is compounded by delays between radiotherapy and surgery. The long delays between referral and DXT highlight a major logistical problem in providing this service in North Trent.

Coloproctology 026

Glutaraldehyde proctitis: the cause of an outbreak of post-sigmoidoscopic diarrhoea

J.M. Hanson, S.M. Plusa, D.A. Browell and W.J. Cunliffe *Queen Elizabeth Hospital, Gateshead, Tyneside*

Background: This study aimed to investigate the role of glutaraldehyde in an outbreak of post-sigmoidoscopic proctitis.

Method: An outbreak of bloody diarrhoea at the start of a flexible sigmoidoscopic screening programme prompted scrutiny of the incidence of this complication and the role of glutaraldehyde in its aetiology. The post-examination questionnaires completed 1 day after the sigmoidoscopy were reviewed for the first 400 subjects and glutaraldehyde levels in the recycled rinse water of the Auto-Disinfector 2 (Keymed) were measured. The incidence of symptoms in the subsequent 400 patients after installation of a new washer was examined.
Results: Five of the patients screened (1·3 per cent) presented to hospital with bloody diarrhoea occurring immediately after a normal examination. Sigmoidoscopy confirmed the presence of proctitis and stool cultures were negative. Symptoms rapidly subsided with steroid enemas. Eight additional patients (2 per cent) recorded similar problems but received no treatment and settled spontaneously. Glutaraldehyde levels rose progressively after each use of recycled 2 per cent glutaraldehyde solution (Cycle 1, 103 mg/l; Cycle 3, 445 mg/l; Cycle 5, 838 mg/l). No cases of proctitis were identified from the questionnaires completed by 400 patients after changing to a washer which did not recycle the rinse water.
Conclusion: Glutaraldehyde levels accumulate in recycled washing fluid and should be considered as a cause of post-sigmoidoscopic proctitis.

Coloproctology 027

Dynamic magnetic resonance defaecating proctography: a new method for assessing anorectal dysfunction?

S.W.T. Gould, G. Lamb, N. Vaughan, A. Wan, W. Gedroyc and A. Darzi *Minimal Access Surgical Unit and Interventional MR Unit, Imperial College School of Medicine at St Mary's, London*

Background: The aim of this study was to develop a technique to investigate defaecatory dysfunction in the interventional magnetic resonance (IMR) scanner. This would combine functional evaluation with soft-tissue imaging in physiological positions without using ionizing radiation.
Method: Eight female patients (median age 63, range 21–83 years) were examined in a 0·5T IMR unit. Six patients had defaecatory difficulty including incomplete evacuation, excessive straining or the need for self-digitation. Examination was normal except for an anterior rectocele in two cases. One patient complained of faecal incontinence (examination revealed poor sphincter tone) and one had full thickness rectal prolapse. The patients were seated on a plastic bedpan with the anorectal region at isocentre and a loop transmit/receive coil under the bedpan. Gadolinium-DTPA (0·1 mmol/kg i.v.) was administered to aid bladder visualization in six patients. Dynamic real-time images were acquired at rest in mid-sagittal and coronal planes (FGR, acquisition time 4 s). Imaging was then performed during maximal squeeze and straining manoeuvres. This was followed by rectal administration of 200 ml of mashed potato reconstituted with 1 per cent gadolinium-DTPA in water. Whilst real-time imaging continued, the patients were asked to empty the rectum and signify when they felt defaecation was complete. The images were assembled into a cine loop for assessment of defaecatory dynamics.
Results: All patients tolerated the procedure. The pelvic organs and soft tissues were clearly visualized and rectal contrast was excellent. The levator ani muscles were visible in the coronal plane. No patient had asymmetrical levator contraction. Bladder visualization was improved by i.v. contrast. The rectal prolapse was clearly visualized. In five of the other patients an anterior non-emptying rectocele was identified, with intrarectal mucosal intussusception in two. Abnormal bladder neck descent was demonstrated in four patients. The patient with sphincter weakness was unable to retain the contrast material. In the final patient, failure of relaxation of the puborectalis (anismus) was demonstrated.
Conclusion: This technique evaluates defaecatory function in a physiological position without exposure to ionising radiation giving information concerning the function of the whole pelvic floor. The technique demonstrated a significant abnormality in patients with defaecatory dysfunction when physical examination was negative or inconclusive.

Coloproctology 028

To operate or not: 2-year outcome of colorectal cancer in a cohort of 1332 patients over 80 years old

B.D. Braithwaite and J.B. Fozard *On behalf of the Wessex Colorectal Cancer Audit working party*

Background: This study aimed to determine the outcome at 2 years of a cohort of patients diagnosed with carcinoma of the colon and rectum between September 1991 and August 1994.
Method: A record of patients diagnosed with colorectal cancer within the Wessex region was interrogated and data analysed. The annual mortality for people over the age of 80 in the Wessex region was 24 per cent.
Results: One thousand and thirty-two patients were identified. Two hundred and ninety-nine patients did not have operative intervention: 82 were dead at the time of diagnosis (74 died as a result of cancer). Of the remaining 217 (mean age 87 years, 69 men), 39 refused operation, 83 were deemed too ill, 39 were inoperable and in the rest no reason was given for non-operative treatment. At 2 years, 159 patients had died (73 per cent). The median time of death was 41 days after diagnosis (range 1–730) and in 124 (78 per cent) the cause of death was attributable to their cancer. Of those who refused operation, 30 per cent were alive at 2 years. In those deemed too ill for intervention, 24 per cent were alive which was similar to the 30 per cent survival in those deemed inoperable. One thousand and thirty-three patients (mean age 85, 43 per cent men) had surgery for their cancer. At operation, 7 per cent had disseminated disease and no resection was done, 6 per cent had local excision, 28 per cent had right, 6 per cent extended right, 2 per cent transverse, 6 per cent left and 11 per cent sigmoid colectomies, while 10 per cent had anterior resection of the rectum, 6 per cent abdominoperineal resection, 2 per cent subtotal colectomy, 7 per cent had a Hartmann's procedure. In 9 per cent the procedure done was not known. Eleven per cent had Dukes classification A, 41 per cent Dukes B, 20 per cent Dukes C staged disease and 22 per cent had liver deposits. Ten per cent of patients developed chest infections. There was an anastomotic leak rate of 2 per cent, 2 per cent postoperative haemorrhage, 2 per cent pulmonary emboli, 3 per cent myocardial infarction, 2 per cent bowel obstructions, 5 per cent wound infections, 1 per cent developed a deep vein thrombosis. The 30-day mortality was 16 per cent. At 2 years 50 per cent of patients had died [median time of death: 157 days after operation (range 0–725)].
Conclusion: These results show that operative intervention for colorectal cancer improves survival in patients over the age of 80.

Coloproctology 029

Aspirin, sulindac and the rectum in familial adenomatous polyposis

S.J. Mills[1,2], J.C. Mathers[1], P.D. Chapman[3], J. Burn[3] and A. Gunn[2] [1]*Departments of Biological and Nutritional Sciences and* [2]*Wansbeck District General Hospital Trust, Ashington, and* [3]*Human Genetics, The University, Newcastle upon Tyne*

Background: This study was designed to investigate the effect of aspirin and sulindac, both non-steroidal anti-inflammatory drugs (NSAIDs), on the rectum of patients with familial adenomatous polyposis (FAP).
Method: Six patients with FAP who had previously undergone colectomy with ileo-rectal anastomosis were randomized to receive 3 months' treatment with aspirin and then sulindac or sulindac and then aspirin. There was a 1-month wash-out between treatments. Videotape recordings of the rectum were taken to permit polyp counts pre- and post-intervention and mucosal biopsies for assessment of crypt cell proliferation by mitosis counting following whole crypt microdissection.
Results: Treatment with both NSAIDs resulted in reductions in crypt cell proliferation in flat rectal mucosa but the effect was more marked with sulindac (decreased from a mean of 11·7 to 6·8 mitotic cells/crypt, $P=0{\cdot}038$) than with aspirin (decreased from a mean of 13·2 to 10·3, $P=0{\cdot}027$). Mean polyp counts also decreased after both sulindac and aspirin treatment, from 15·7 to 10·2 and 13·1 to 12·1, respectively, but this did not reach statistical significance.

Conclusion: Both aspirin and sulindac reduce proliferative activity in the macroscopically normal mucosa as assessed by whole crypt microdissection. This does not result in a concomitant regression of adenomatous polyps over the time scale studied.

Coloproctology 030

Training in coloproctology. How much actually takes place?

R.J. Aitken and S.J. Nixon *Lothian Surgical Audit, Royal Infirmary, Edinburgh*

Background: To assess trainee experience and consultant supervision in coloproctology in a UK city.
Method: Coloproctology operations undertaken during 1996 were retrieved from a prospective regional database containing all general surgical operations. The database covered three teaching hospitals, 15 consultants, 11 specialist registrars (SpR) and 11 SHOs.
Results: A total of 2464 coloproctology operations (excluding appendix operations) were undertaken. Eight hundred and seventy-two (35 per cent) were performed by a consultant who assisted in another 15 per cent. One thousand and seven (41 per cent) were undertaken by a registrar and the consultant assisted in one third. Two hundred and fifty-five (10 per cent) were undertaken by an SHO and the consultant assisted in 20 per cent. Individual consultant supervision ranged from 7 to 29 per cent. In a larger audit consultants assisted in 19 per cent of colorectal cancer resections and their supervision appeared to be increasing. Analysis of representative operations on the general surgical units suggested that an SpR would, on average, undertake 1·4 Hartmann's resections per year (50 per cent consultant supervised) and an SHO 3·1 haemorrhoidectomies per year (33 per cent consultant supervized).
Conclusion: This study suggested that trainees received minimal coloproctology training from their consultants. There is considerable scope for consultants to increase their supervision but this will have significant service implications.

Coloproctology 031

Towards early appropriate referral for the diagnosis of colorectal bleeding

P.S. Basnyat, C. Button, P. Banerjee and M.E. Foster *East Glamorgan General Hospital, Mid Glamorgan*

Background: The aim of this study was to audit the quality of general practitioner's (GP) referral letters with regards to rectal bleeding and to implement necessary changes to improve the data presented.
Method: Rectal bleeding referral letters between January 1996 and December 1996 from all GPs in a specific area were reviewed and scored using a simple scoring system. An educational programme in respect to colorectal disease and rectal bleeding was implemented to involve all GPs and practice nurses.
Results: Sixty-four (37 from men) referral letters have been analysed. Details of colorectal symptoms with duration and clinical examination findings in the referral letters were allocated appropriate points (maximum score being 17 points). The mean score of the letters was only 3·2 (range 0–15) points. Only 12 GPs had documented evidence of abdominal examination and 24 had documented rectal examination findings. Hospital investigations confirmed four cancers, 11 polyps, five colitis, one solitary rectal ulcer, 10 diverticular disease, 26 haemorrhoids, six fissures and two fistula-in-ano. Three patients were inappropriately referred and had no colorectal symptoms (back pain, heartburn, ovarian mass). PSB and CB have visited all 18 practices and spoken individually to 36 GPs (out of 45) and 31 nurses. A total of 136 miles have been covered and 42 h have been spent directly on educational meetings. After completion of GP visits a symposium was organized to answer any remaining questions and to develop further the theme of colorectal cancer. Eighteen GPs attended the symposium and over 90 per cent found it very useful and educational.
Conclusion: The educational programme has been well received by both GPs and nurses. Re-evaluation of referral patterns will indicate the success of the educational programme and, in fact, recent referral letters have been of high quality.

Coloproctology 032

Controlled intraoperative water testing of left-sided colorectal anastomoses: are ileostomies avoidable?

J.M.D. Wheeler and J.M. Gilbert *Department of Surgery, Wexham Park Hospital, Slough, Berkshire*

Background: Anastomotic leakage is a major problem in colorectal surgery, and previous studies have suggested that intraoperative identification of leaks allows repair at the time of surgery. This study examined whether testing allowed a defunctioning ileostomy to be safely omitted.
Method: One hundred and two consecutive patients underwent left-sided colorectal resection (52 males and 50 females with a mean age o 65·7, range 16–89, years). Following completion of anastomosis, it integrity was tested by running saline into the rectum, using a manometer to a maximum distending pressure of 30 cm water. Any leaks were repaired and the anastomosis re-tested. All patients underwent a contras enema on the eighth postoperative day. A defunctioning ileostomy wa only performed if the anastomosis could not be shown to be leak-proo on testing.
Results: Twenty-one (20·6 per cent) patients failed the initial leak tes although only two of these went on to have a clinical leak. Sixteen (16· per cent) had a leak on radiological testing, and there was clinical evidence of a leak in five (4·9 per cent) patients. Two defunctionin ileostomies were performed. There were three (2·9 per cent) deaths bu none of these had a leak on radiological testing.
Conclusion: Incomplete anastomoses were successfully corrected intraoperatively. A defunctioning ileostomy was avoided in 98 per cent o cases.

Coloproctology 033

Systematic review of laparoscopic surgery for malignant colorectal disease

L. Yong, M. Deane, J.R.T. Monson and A. Darzi *Minimal Access Surgical Unit, St Mary's Hospital, London and Academic Surgical Unit, University of Hull, Hull*

Background: A systematic review of the current literature on laparoscopic surgery for colorectal malignancy was undertaken to compare th complications, postoperative outcome, survival and cost of laparoscopi surgery for colorectal malignancy with open surgery.
Method: Publications from January 1991 to March 1997 were located b electronic database, manual and reference search. Inclusion criteria wer used to select the most robust studies which were weighted by hierarchy o evidence for the review. Data were abstracted to a database for analysis.
Results: Of the 157 publications located, only 42, representing 341 patients, were selected for inclusion into the review. All were low in th hierarchy of evidence (32 were case series reports). Only 13 of the 4 papers concentrated specifically on malignant disease. The average patien age was 63·2, equal male to female ratio. The most common contraindications were bulky tumour masses, previous operations or obesity. Th operative conversion rate for a range of procedures was 17·2 per cen Intraoperative complication rate was 4·2 per cent, postoperative morbidit was 11·3 per cent and 30-day mortality was 1·64 per cent. No circumferential margins were reported; the average distal margin was 5·7 cm an average lymph node harvest was 10·4. Recurrence rates, reported by ha the papers, was 8·4 per cent, one tenth were port-site metastases. We wer unable to assess critically recovery benefits, long-term survival or cost.
Conclusion: Studies of low hierarchy of evidence continue to be published 6 years after the first report of laparoscopic colorectal surgery wit the majority of papers representing feasibility studies which cannot b generalized and are highly variable in the standard of reporting, reflectin a non-standardized approach to the reporting of a new technique. Th benefits of laparoscopic surgery for malignancy remain unproved an should only be undertaken in the context of a multi-centre randomize controlled trial.

General 017

A prospective comparative audit of emergency surgical workload at a district general hospital over changing times

J.R.A. Walker, J. McLaren, D. Signorini and D.A.D. MacLeod
Department of General Surgery/Urology, St John's Hospital, Livingston, West Lothian

Background: This study aimed to assess the impact of recent national changes on surgical training at a district general hospital.
Method: Five hundred and fifty consecutive emergency surgical referrals for the 9-week period 1 September to 3 November 1995 and 543 consecutive emergency surgical referrals for the same 9-week period in 1996 were studied. Statistical analysis was performed using the χ^2 test.
Results: At senior house officer level exposure to acute surgical referrals was reduced by 52 per cent and at career specialist registrar level by 4 per cent. In 1996, 3 per cent fewer patients were operated upon and there was a 10 per cent fall in attendance of the admitting trainee at these operations.
Conclusion: The results indicate a significant ($P<0{\cdot}001$) deleterious impact of the changes between 1995 and 1996 on training opportunities in the surgical department of a district general hospital at senior house officer level.

General 018

A prospective audit of inguinal hernia in childhood

C.P. Driver, J. Bowen, J. Bruce, A. Bianchi, C.M. Doig and A.P. Dickson *Royal Manchester Children's Hospitals NHS Trust, Hospital Road, Pendlebury, Manchester*

Background: The aim was to assess the management of inguinal hernia repair in children.
Method: All children admitted for repair of an inguinal hernia were audited prospectively, assisted by the clinical audit department.
Results: In a 4-month period, 135 children were identified. Of these, 72 (53 per cent) were under 1 year of age, of whom 39 (54 per cent) had been born prematurely. In 45 (33 per cent) cases, the child required emergency admission for suspected incarceration of the hernia. In those under 1 year, however, 38 (53 per cent) were emergencies. A consultant surgeon performed or was present at 73 (54 per cent) cases and in 45 (63 per cent) of those children under 1 year; a consultant anaesthetist was present at 109 (81 per cent) cases and 63 (88 per cent) of those under 1 year. Complications related to surgery were identified in six (4 per cent) children, none of which required a further procedure. The mean length of hospital stay in all children was 1·6 days (range 1–4 days) for elective admissions and 2·4 days (1–7) for emergency cases. In those under 1 year of age, this was 1·8 (1–4) and 3·5 (1–7) days, respectively. This longer stay in emergency cases was due mainly to the difficulty in finding an appropriate theatre session. Prematurity was the commonest cause for an overnight stay.
Conclusion: When planning hernia surgery in children, half could be expected to stay for at least one night. Inguinal hernias in infants continue to require emergency treatment and urgent referral of children in this age group to a paediatric surgeon is once again recommended.

General 019

Diagnostic laparoscopy for appendicitis: only useful in young women

I.P. Mackie, B.S. Taylor, R. Jarman, F.G. Bergin, A.L.G. Peel and D.J. Leaper *North Tees General Hospital, Stockton-on-Tees, Cleveland*

Background: A prospective audit of diagnostic laparoscopy for patients with suspected appendicitis was revisited after 2 years to 'close the loop' for effective clinical guidelines. Open appendicectomy is encouraged as a training operation at this Trust.
Method: Between January 1995 and December 1996, 282 patients were taken to theatre with a diagnosis of suspected acute appendicitis. Of these 145 (51 per cent) had laparoscopy; 116 had subsequent appendicectomy. The remaining 137 patients (49 per cent) had appendicectomy without preliminary laparoscopy (the majority being men or children with clear signs and symptoms).
Results: Twenty-nine patients were spared unnecessary appendicectomy following laparoscopy, all but one being women of child-bearing age. However, 116 patients had appendicectomy of whom 31 (21 per cent) had a clinically and histologically normal appendix; 85 (59 per cent) were inflamed with 23 (16 per cent) perforations. Of those who did not have laparoscopy 29 (21 per cent) had a normal appendix removed, 108 (79 per cent) were inflamed with 35 (32 per cent) perforations. Operating times were prolonged in the laparoscopy group (62 min; range 2–240 min) compared to open operation alone (53 min; range 15–250). There were no differences in length of post-operative stay (4·2 days, range 1–16 versus 4·6 days, range 1–17).
Conclusion: Although the negative appendicectomy rate was similar it is clear that women of child-bearing age benefit from preliminary diagnostic laparoscopy to avoid unnecessary operation. For all other patients open appendicectomy is appropriate and should be retained as a training operation.

General 020

Delivery of surgical care in a district general hospital without High Dependency Unit facilities

R.P. Coggins *Birch Hill Hospital, Rochdale*

Background: Many hospitals lack the facilities for high dependency care, and patients requiring this level of care are nursed on the surgical ward. The aim of this study was to assess the extent of this problem in a district general hospital, looking at the impact of providing High Dependency Unit (HDU) care at ward level.
Method: A 28-bed surgical ward was studied for 39 consecutive days. Patients were assessed as being either appropriately placed (routine) or inappropriately placed (HDU). Nursing interventions and observations over each 24-h period were recorded for the most dependent patient in each group.
Results: Data were collected for a total of 1092 bed days. Median bed occupancy was 22 patients (78 per cent). Inappropriately placed HDU patients accounted for 55 bed days (5·04 per cent, average 1·4 patients/day). These patients required more intensive nursing than routine patients. HDU patients received more observations during 24-h than routine patients (mean 11·33 and 4·15, respectively, $P<0{\cdot}005$). The number of observations recorded for a routine patient in 24-h fell when an HDU patient was nursed concurrently on the ward (average 5·09/24 h, falling to 3·77/24 h in the presence of an HDU patient, $P<0{\cdot}02$).
Conclusion: HDU patients require more intensive nursing care than routine surgical patients. The nursing of HDU patients on the ward adversely affects the quantity of care available for less dependent patients.

General 021

A profile for change: improved operating theatre utilization

C.J. Vickery, A.J.M. Brodribb and S. Ashley *Department of Surgery, Derriford Hospital, Plymouth, Devon*

Background: In keeping with the findings of the Bevan report of 1989 towards greater operating theatre efficiency, we set out to design and test a software system aimed at profiling the annual performance of each individual inpatient operating session for nine general surgeons in a large district general hospital.

Method: A software system was designed to employ standard information collected in an existing theatre database (ORSOS) and to display the results for each operating session for a year in simple graphic and tabular form on a single sheet of paper. Data were produced concerning theatre time utilization ('set-up time', 'operating time', 'de-set-up time', 'cold table time', early and late starts and finishes), number of patients and case-mix by BUPA category, intermediate equivalent procedures per session, total lists used and cancelled cases per annum. These data completed a profile of the working patterns of each individual operating list and hence theatre team (surgeon, anaesthetist, nursing and ancillary staff), enabling identification of persistent problems of case-mix, case-load, cancellations and surgical, anaesthetic, nursing or portering delays. Individual profiles were distributed to surgeons, anaesthetists, theatre sisters and theatre managers involved with each session, for interpretation, discussion and subsequent implementation and assessment of any changes towards improved practice.
Results: After running the profiles for two years, there has been an overall increase of 3·5 per cent in the mean intermediate equivalent value of each session, a 12 per cent reduction in lists finishing more than 30 min early and an increase in the total number of cases of 9 per cent, with a 10·7 per cent reduction in cancelled cases. The percentage utilization of theatre sessions for individual surgeons increased in a significant majority to over 90 per cent, representing a 5·3 per cent increase in overall theatre utilization (91·3 per cent), a calculated saving of £100,000 in reduction of wasted theatre time.
Conclusion: From the outset it was determined that the project would be strictly facilitatory rather than judgmental and through individual and group discussion of these profiles, problems have been addressed and changes implemented to improve overall operating theatre efficiency.

General 022

Longevity of surgeons

M. Al-Fallouji, A. Gupta and S. Hameed *Department of Surgery, Pilgrim Hospital, Boston, Lincolnshire*

Background: The aim of this study was to reveal the mean retirement and survival (MS) of surgeons in relation to other doctors.
Method: A study of 1488 obituaries reported in consecutive British Medical Journal issues was made from February 1992 to November 1995.
Results: General practitioners led the list of reported deaths (558 doctors) with MS of 74·49 years, followed by physicians (326) 77·94 years, then surgeons (226) 76·05 years. Others included ophthalmologists 77·58, and accident/emergency surgeons 64·5, psychiatrists (70) 71·6, anaesthetists (65) 73·34, pathologists (62) 77·19, obstetricians/gynaecologists (60) 74·89. There were eight medical students and trainees with the shortest MS of 24 years. The 10 reported hospital administrators have the longest MS of 78·68 years. Of 226 surgeons, 41 died while working (18·5 per cent) with MS of 55 years, 17 retired before the age of 65 (7·5 per cent) with a late MS of 11·82 years, 161 retired at the age of 65 (71 per cent) with a late MS of 15·06 years, and seven continued their private practice after the age of 65 (3 per cent) with a late MS of 10·85 years.
Conclusion: Surgeons survive well as compared to other doctors, but physicians and administrators are the longest survivors. There is no clear evidence that surgeons who retire early survive longer. Retirement at 65 can still yield an optimal survival.

General 023

When is the specialist surgeon really trained?

D. Sutton, J. Wayman, D. Karat, N. Hayes and S.M. Griffin *The Oesophago-Gastric Cancer Unit, Newcastle General Hospital, Newcastle upon Tyne*

Background: Surgical training and experience are frequently claimed to influence surgical results. The aim of this study was to quantify any improvement in an individual surgeon's performance in one operation over a period of 8 years from initial appointment to date.
Method: Patients undergoing Ivor–Lewis subtotal oesophagectomy performed by a single surgeon (SMG) between November 1989 and January 1997 were identified from a prospectively compiled oesophageal cancer database. Age, sex, smoking and alcohol history, ASA grade, operative time (abdominal, thoracic and 'one lung time'), blood loss, transfusion requirements (intraoperative and total), extent of lymphadenectomy (number of lymph nodes sampled, ITU stay, postoperative complications, pathological stage, grade and survival were studied. Statistical comparison was carried out using ANOVA and χ^2-squared tests.
Results: The records of 150 patients were identified for analysis; the cohort was split into five groups of consecutive patients. Each of the groups was comparable for age, sex, smoking and alcohol histories, ASA grade, and histological stage of disease. Analysis of the variables pertaining to operation revealed a significant improvement with time:

Cases	One lung time (min)	Blood loss (ml)	Transfusion (units)	ITU stay (days)	In-patient stay (days)	Lymph nodes sampled (*n*)
1–30	120·2 (6·3)	1186·7	2·07 (0·37)	4·89 (0·88)	27·8 (2·3)	8·03 (0·78)
31–60	121·6 (3·8)	1332	1·64 (0·51)	3·93 (1·4)	22 (2·7)	11·61 (1·6)
61–90	110·1 (3·9)	815·3	0·31 (0·15)	2·73 (0·57)	29 (5·17)	12·29 (1·05)
91–120	104·1 (5·6)	790·7	0·29 (0·14)	2·75 (1·06)	22·1 (5·36)	15·96 (1·36)
121–150	99·7 (7·5)	879·2	0·76 (0·21)	1·08 (0·13)	16·1 (0·70)	15·29 (1·5)
P value	0·03	<0·01	<0·001	0·02	0·04	0·002

Conclusion: This study reveals a continuing improvement in an experienced surgeon's operative performance over 8 years. With the current trend to a shorter training for surgeons, there is a case for continuing supervision of the 'fully trained' surgeon undertaking complex procedures.

General 024

Audit of the 841 deaths from oesophageal or gastric cancer on surgical wards in Scotland 1994–1996

S.Y. Soon*, F. Marjoribanks†, S.J. Nixon† and A.M. Thompson*† **Department of Surgery, Ninewells Hospital, Dundee, †Scottish Audit of Surgical Mortality, Royal College of Surgeons, Edinburgh*

Background: The Scottish Audit of Surgical Mortality (SASM) collected data on all 841 patients (395 with oesophageal cancer, 446 with gastric cancer) who died on surgical wards from 1994 to 1996.
Method: Five hundred and six (60 per cent) were <70 years (range 30–96 years), 61 per cent were men and 55 per cent were admitted as an emergency. Emergency admission increased with age. Seventy per cent of patients were ASA 3 or greater. The cause of death was cancer in 53 per cent but cardiopulmonary complications in 21 per cent; 451 died without an operation. A post-mortem was done in only 18 per cent and provided additional information in 33 per cent of patients.
Results: Case note review showed close agreement between the surgical and anaesthetic assessors. From surgical assessment, the choice of operation (3·9 per cent) preoperative management (2·8 per cent), intraoperative management (11·1 per cent), or postoperative management (8·8 per cent) contributed to death. There were technical problems in 20 per cent of the operations. Anaesthetic criticisms included the failure to use ITU/HDU (in 22·5 per cent) and postoperative management in 8·5 per cent. Adverse surgical decisions contributed to death in 16·2 per cent (1994) falling to 12·8 per cent (1996), and caused death in 5·1 per cent (1994) falling to 0·7 per cent (1996); anaesthetic factors contributed to death in 10·1 per cent and caused death in 1·0 per cent.
Conclusion: This SASM Audit highlighted problem areas in the surgical management of patients with oesophageal and gastric cancer and resulted in improved surgical decision-making. There remains room for improvement particularly for intraoperative and postoperative care in patients with operable disease.

General 025

Surgical patients with multiple-resistant *Staphylococcus aureas* infection: a P-POSSUM analysis

K.V. Menon, M.S. Whiteley, P. Burden and R.B. Galland *Royal Berkshire Hospital, Reading*

Background: This study aimed to study the significance of multiple-resistant *Staphylococcus aureas* (MRSA) infection in surgical patients using the P-POSSUM scoring system.
Method: All surgical patients were prospectively scored using the P-POSSUM. A subset of these patients with MRSA infection were analysed using P-POSSUM predicted mortality, comparing physiological and operative severity score with non-MRSA surgical patients and length of hospital stay with P-POSSUM-matched non-MRSA controls.
Results: Thirty of the 1132 patients were MRSA positive and of these five died giving a P-POSSUM observed/expected deaths ratio of 1·7 (not significant; 95 per cent, CI –0·24–0·10). The P-POSSUM physiology score of 30 MRSA-positive patients compared to the non-MRSA group (n = 1102) was significantly worse (20·9 versus 17·4; 95 per cent, CI 1·09–5·95) as was the operative severity score (15·6 versus 9·2; 95 per cent, CI 4·40–8·42). The length of stay for MRSA-positive patients was significantly longer than P-POSSUM-matched controls. For mortality risk <5 per cent (n = 16), mean hospital stay (days) MRSA-positive controls = 23·8 versus 5·9; 95 per cent, CI 2·42–33·48. For mortality risk >5 per cent (n=9), mean hospital stay (days) MRSA-positive controls = 33·4 versus 13·4; 95 per cent, CI 5·50–34·64.
Conclusion: MRSA infection in surgical patients does not increase mortality. However, patients who have contracted MRSA infection are more debilitated, undergo a greater surgical insult and stay longer in hospital compared to the non-infected controls.

General 026

A dedicated NHS hernia service improves patient outcome and cost-effectiveness

D.H. Bennett, C. Porter and A.N. Kingsnorth *Department of Surgery, Derriford Hospital, Plymouth, Devon*

Background: A hernia service was commenced at Derriford Hospital on 1 October 1996 following a poor star rating for its performance in day-case hernia surgery. The rationale was to increase the number of patients undergoing day-case, local anaesthetic surgery and to improve cost-effectiveness.
Method: The number of patients undergoing day-case and local anaesthetic repair since the commencement of the hernia service to July 1997, was identified. A hernia satisfaction questionnaire was sent to a random sample of 50 patients who had had their hernia repaired by the hernia service and 50 patients who had had their hernia repaired by another team.
Results: In its first 9 months, 207 men were referred to the service and 156 (145 primary and 11 recurrent) had undergone hernia repair, 117 (75 per cent) went home the same day. Local anaesthesia (LA) was used in 128 (82 per cent), 110 (86 per cent) of whom went home the same day compared to seven (30 per cent) who received a general anaesthetic (GA). Completed questionnaires were received from 41 (82 per cent) hernia service patients and 36 (72 per cent) patients treated by another team. Results were analysed for 36 patients from each group. Of the second group, 13 (36 per cent) received LA and 14 (39 per cent) were treated as a day-case. Hernia service patients experienced a mean pain score of 4·7 (range 0–10) compared to 5·7 (range 0–10) (P = 0·07) for the other group. Hernia service patients required postoperative analgesia for a mean of 2·8 days (range 0–6 days) compared to 5·9 (0–21 days) (P<0·01) in the other group. Similarly, hernia service patients experienced wound pain for a mean of 3·4 days (0–21) compared to 8·1 (0–30) (P<0·01) for the other group. Normal activity was also resumed at an earlier stage by patients treated by the hernia service (mean 10·8 days compared to 17·6 days, P<0·01).
Conclusion: These results demonstrate that the instigation of a hernia service has resulted in more patients undergoing local anaesthetic, day-case surgery with less postoperative pain and an earlier return to normal activity. Increasing the number of day-case hernia repairs from 39 per cent to 75 per cent in this hospital (800 adult hernia repairs annually) represents an annual saving of over £70 000.

General 027

Analgesia in acute abdominal pain: an audit of current surgical practice

I.S. Tait, M.V. Gogot and A. Cuschieri *Department of Surgery, Ninewells Hospital and Medical School, Dundee*

Background: Traditional teaching states that analgesia should be withheld in patients with acute abdominal pain for fear of masking physical signs. Others argue that such practice amounts to suboptimal clinical management. As approximately 25 per cent of all surgical admissions require treatment of acute abdominal pain, this study aimed to: i) determine local surgical practice for pain relief; and ii) investigate patient, clinician and hospital dependent factors which might influence variability in patient waiting times for analgesia.
Method: One hundred emergency admissions with acute abdominal pain were randomly selected for analysis. Time of analgesia administration, clinical setting of first dose, and clinical diagnosis were documented. Pain severity was determined by visual analogue patient self-assessment. Local surgical opinion as to the appropriate timing of analgesia was acquired by questionnaire, and determined for all grades of surgical staff (n = 35 of 36).
Results: Forty per cent of patients received analgesia within 1 h of admission, 17 per cent between 1–2 h, but 43 per cent waited 2–20 h for first dose of analgesia. Analgesia was not withheld in any patient to facilitate diagnosis. Eighty-four per cent of patients (n = 84) had severe pain and 16 per cent moderate pain. Mean waiting time for analgesia in severe pain was 2·3 h versus 6·3 h for moderate pain (P<0·0001; Wilcoxon). However, 33 per cent with severe pain waited >2 h for analgesia. Clinical diagnosis did not influence the urgency with which analgesia was administered, regardless of the pathology. Local surgical opinion favoured early analgesia after the initial SHO assessment ('yes' 88 per cent; n = 30), even in the absence of a firm diagnosis ('yes' 79 per cent; n = 37). The majority of surgical staff believe that early analgesia does not mask physical signs ('no' 62 per cent; n = 21). However, junior surgical staff (SHOs) were most likely to withhold analgesia in the accident and emergency department (A&E) for fear of masking physical signs. Patients leaving A&E without analgesia waited on average 5·7 h for first dose of analgesia compared with 0·9 h for those receiving analgesia in A&E (P<0·0001; Wilcoxon). Ninety-two per cent of GP referrals did not receive pre-hospital analgesia.
Conclusion: Forty-three per cent of admissions with acute abdominal pain wait too long, despite local surgical opinion advocating early analgesia. Severity of pain and underlying pathology do not influence early pain relief. The huge variability in patient waiting-time for analgesia results from omission of analgesia in A&E, and a fear of hampering clinical management by junior surgical staff at SHO level.

General 028

Surgical assessment wards: the way forward?

A. Abidia and D. Chang *Blackburn, Hyndburn & Ribble Valley NHS Trust*

Background: The aim of this study was to use the general surgical bed complement more efficiently and to improve emergency services. Emergency surgical admissions are concentrated on one ward, the Surgical Assessment Ward (SAW). We describe the results and impact of the SAW since its introduction in 1996.
Method: Data were collected and analysed for all surgical emergencies for the year before SAW was opened (1994–1995) and the year since its introduction (1996–1997).

Results: The total length of stay for emergency admissions has decreased from 14 281 to 13 809 despite a 2·6 per cent increase in the number of admissions. There was a 21 per cent increase in the number of patients allowed home within 24 h of assessment in 1996–97. Nevertheless, there was an increase in the number of emergency procedures performed from 1342 to 1442. The mean number of consultant visits to the SAW per day was three. There was an increase (10·4 per cent) in the total number of elective surgical admissions from 4596 to 5076 and an increase in the percentage mean bed occupancy in general surgical wards from 73 per cent to 80 per cent.

Conclusion: The SAW concentrates emergency services on one ward, thereby facilitating admissions by GPs and increasing the efficiency of elective surgical work. The implementation of the SAW may have saved £84 300 in the year 1996–1997.

General 029

Validation of the P-POSSUM surgical scoring system in a district hospital

M.S. Whiteley, D.R. Prytherch, T.R. Magee and R.B. Galland
Royal Berkshire Hospital, Reading, Berkshire

Background: P-POSSUM (Portsmouth-POSSUM) was described in 1996 as an improvement on the POSSUM surgical scoring system (POSSUM = Physiological and Operative Severity Scoring System in the enUmeration of Morbidity and mortality). The aim of this study was to assess the performance of P-POSSUM in a district hospital to check the validity of its predictions in an independent unit.

Method: Between November 1996 and April 1997, 1132 general surgical patients who underwent an operation were prospective scored by the P-POSSUM system. End-points were death or discharge. One audit clerk, specifically employed for this project, collected the P-POSSUM data daily and added it to a dedicated computer database.

Results:

Risk range	Number at risk	Mean risk	Predicted deaths	Reported deaths	χ^2
0–<5	1025	0·9	9	7	0·45
5–<15	65	8·74	6	7	0·18
15–<50	34	25·88	9	7	0·60
50–100	8	67·25	5	3	2·13
0–100	1132	2·27	29	24	$P = 0{\cdot}50$ (4 d.f)

Conclusion: There was an excellent correlation between the number of reported and P-POSSUM predicted deaths. This study validates the mortality prediction by P-POSSUM in a second district hospital.

General 030

Current surgical practice in the management of inguinal hernias in the UK

D.C. O'Riordan, M. Morgan, A.N. Kingsnorth, N.A. Black, S. Ambrose, P. Jones, S. Raimes, R. Taylor, D. Watkins and H.B. Devlin *On behalf of the Steering Committee, The National Groin Hernia Outcomes Project, The Surgical Epidemiology & Audit Unit, The Royal College of Surgeons of England*

Background: This study aimed to establish current surgical practice in the management of inguinal hernia in NHS patients and to compare this with the guidelines published by the Royal College of Surgeons of England.

Method: All surgeons and hospitals in two regions (South Thames and Northern & Yorkshire) performing groin hernia repair were identified and invited to participate. Participating surgeons completed a questionnaire for all patients over 18 years undergoing elective and emergency inguinal hernia between July and October 1996.

Results: Three hundred and eighty-five surgeons in 131 hospitals were identified. Of these, 118 hospitals were included and 276 of 368 (75 per cent) surgeons in these hospitals agreed to participate. Questionnaires in 5038 of 5556 patients were returned (90·7 per cent) of whom 4212 had inguinal hernia repairs in the NHS. One hundred and seventeen (2·8 per cent) operations were performed on urgent or emergency cases. A consultant operated on 1554 (37·4 per cent) patients and 259 (6·1 per cent) of operations were performed by unsupervised SHOs. A total of 2416 (61·1 per cent) patients received antibiotics. Two hundred and twenty-seven (5·4 per cent) operations were performed using local anaesthesia and 1745 (42·5 per cent) were as planned daycases. Consultant surgeons did not perform significantly more day-case operations. The operative techniques are shown in the Table. Consultant surgeons performed 282 (18·2 per cent) of operations laparoscopically ($P < 0{\cdot}001$ χ^2).

Operative technique	Number (%)
Shouldice	430 (10·2)
Lichtenstein	2944 (69·9)
Stoppa	64 (1·5)
Bassini	390 (9·3)
Nylon (or similar) darn	367 (8·7)
Prosthetic plug	53 (1·3)
Total laparoscopic	407 (9·7)
TAPP laparoscopic	315 (7·5)
TEP laparoscopic	82 (1·9)
Other laparoscopic	10 (0·2)

Conclusion: There has been a large change in practice in recent years that coincides with publication of the RCS guidelines. There was very widespread uptake of open mesh repair. The use of local anaesthesia is very low. Many patients had prophylactic antibiotics despite there being little evidence of benefit. Laparoscopic surgery was carried out by senior surgeons which may improve outcomes but might have implications for training.

General 031

Is your anaesthetist nauseating?

R.D. Howell, B.D. Braithwaite and S.D. Parvin *Royal Bournemouth and Christchurch Hospital, Bournemouth*

Background: Postoperative nausea and vomiting (PONV) can increase hospital stay and decrease patient satisfaction. The aim of this study was to reduce the incidence of PONV after varicose vein (VV) surgery.

Method: Some 57 patients (39 women, median age 54 years) had VV surgery performed by a single consultant vascular surgeon. Twenty-one patients had a unilateral procedure, 33 bilateral and three had surgery for recurrent VV. All patients were anaesthetized by one of three consultant anaesthetists (A, B and C) who used different techniques. No attempt was made by the surgeon to influence the anaesthetic. After surgery, each patient gave categorical answers about PONV. The anaesthetists were given the results and told that it would be repeated without their knowledge. One month later, 42 patients (median age 48 years, 34 female, 16 unilateral, 24 bilateral, two recurrent) were entered into an identical study. Results were analysed by χ^2.

Results: In the first study, anaesthetist A treated 15 patients of whom six (40 per cent) felt nauseated and one (7 per cent) vomited, B treated 26 patients, 15 were nauseated (57 per cent) and five (19 per cent) vomited and C treated 16 patients, one was nauseated (6 per cent), none vomited. C produced significantly less nausea compared with both B ($P = 0{\cdot}03$) and A ($P = 0{\cdot}0009$). No significant differences were observed between A and B and there were no differences in vomiting. In the second study all three anaesthetists used the technique employed by C. A treated 11 patients, one (9 per cent) had nausea, none vomited, B treated 17 patients, one (6 per cent) had nausea, none vomited, C treated 14 patients, one (8 per cent) had nausea, none vomited. There was an improvement from the previous study for both A ($P = 0{\cdot}08$) and B ($P = 0{\cdot}0006$).

Conclusion: This study shows that surgeons can influence the outcome of anaesthesia to the benefit of their patients.

Vascular 041

Outcome in patients requiring renal support following repair of ruptured aortic aneurysm

R.P. Singam, A. Nasim, J. Barrett, J.F. Feehally, P.R.F. Bell and R.D. Sayers *Department of Vascular Surgery and Department of Nephrology, Leicester General Hospital NHS Trust, Leicester*

Background: The aim of this study was to assess the outcome of patients requiring renal support following repair of ruptured aortic aneurysm.
Method: Retrospective audit of all patients developing acute renal failure following emergency aortic aneurysm repair between 1984 and 1996.
Results: Sixty-five patients developed acute renal failure following emergency aortic aneurysm repair over 13 years, with a median age at presentation of 68 (range 49–84 years). The overall 30-day mortality in this group of patients was 75 per cent. Three prognostic indicators were identified as being associated with a significantly higher mortality rate in these patients: the presence of vascular disease at presentation (other than the aneurysm), the need for an additional intraoperative procedure and the presence of one or more failing organ systems. The mortality increased to 95 per cent when all three factors were present. Renal replacement therapy was required for a median of 11 (range 0–41 days) in non-survivors and median period of 19 (range 1–46 days) in survivors. Sixteen survivors were discharged from hospital after a median stay of 49 (range 10–137 days). Postoperative serum creatinine was >130 µm/l in 11 of these patients. A further patient was dialysis dependent. Survival following discharge was 100 per cent at 6 months.
Conclusion: Acute renal failure complicating ruptured abdominal aortic aneurysm is associated with a 75 per cent in-hospital mortality. The mortality rate increases to 95 per cent if there is a history of vascular disease, an additional operative procedure is performed and one or more organs fail postoperatively.

Vascular 042

Ruptured abdominal aortic aneurysm in the octogenarian

E. El-Seedawy, S. Naidu, R.J. Holdsworth and P.T. McCollum
Vascular Unit, Ninewells Hospital, Dundee

Background: The role of emergency aortic surgery for ruptured aneurysm in the over 80 years age group is controversial with some advocating an 'all-comers' policy, some a selective policy and others suggesting that surgery is usually not justified. We wished to examine the outcome of an 'all-comers' policy to ruptured aneurysms in the octogenarian.
Method: All confirmed ruptures in patients over 80 at the time of presentation (mean age 83·3 ± 2·4; range 80–88 years) to one vascular surgeon were included in this study over a 5-year period. Twenty-six patients were identified, of whom three patients did not have surgery, one due to pre-theatre death and two patients who had known terminal illness.
Results: In 23 elderly patients having surgery there were 15 survivors at 30 days (65 per cent). Perioperative deaths were due to myocardial infarct (3), multi-system failure (3) and respiratory failure (2). There was no significant difference in mortality rate between patients in this study and a contemporaneous series of 117 ruptures of all ages. Mean follow-up was 3·3 years with four further deaths occurring at 3 months, 5 months and 60 months after discharge.
Conclusion: These data suggest that emergency repair of ruptured AAA in the elderly patient carries a similar initial chance of survival compared to a younger patient and is entirely justified.

Vascular 043

Ruptured abdominal aortic aneurysms: perioperative factors influencing outcome

M. Delbridge, E.P.L. Turton, K.G. Mercer, D.C. Berridge, P.J. Kent, R.C. Kester and D.J.A. Scott *Department of Vascular Surgery, St James's University Hospital, Leeds*

Background: Comparative audit reveals a considerable variation in mortality from emergency repair of ruptured abdominal aortic aneurysm that is often attributable to case mix. This study aimed to identify the most important factors that are predictive of early mortality following emergency repair of ruptured abdominal aortic aneurysm.
Method: The hospital records and operative notes of 102 consecutive patients, who underwent emergency surgery for ruptured AAA, were reviewed retrospectively. Ten perioperative factors were analysed as previously identified indices of subsequent mortality: age and sex, preoperative systolic blood pressure, haemoglobin, haematocrit, amylase, creatinine, platelet count and activated partial thromboplastin time (APTT), preoperative cardiac arrest, and the type of rupture (intra- or retroperitoneal). χ^2 test† or logistic regression analysis* was used to compare outcome variables.
Results: The 30-day mortality was 53 per cent. Intraperitoneal rupture was the greatest independent predictor of mortality (intraperitoneal 95 per cent, retroperitoneal 27 per cent; $P<0{\cdot}001$, OR 18·7)*. Other variables significantly associated with mortality included: preoperative coagulopathy (platelets $<100 \times 10^9$/l and APTT >60 s $P<0{\cdot}001$, OR 15·7)*, preoperative cardiac arrest ($P=0{\cdot}002$, OR 11·5)*, systolic blood pressure <91 mmHg ($P<0{\cdot}001$, OR 9·46)*, haemoglobin <8 g/dl ($P<0{\cdot}001$)†, haematocrit <25 per cent ($P<0{\cdot}001$)†, age >76 years ($P<0{\cdot}01$)†, and amylase >340 µ/l ($P<0{\cdot}005$)†.
Conclusion: In this series intraperitoneal rupture was the greatest predictor of early mortality. It should be reported in future series of emergency aneurysm surgery for the purposes of comparative audit.

Vascular 044

Endovascular abdominal aortic aneurysm repair attenuates the metabolic response associated with conventional surgery

J.R. Boyle, S. Goodall, J.P. Thompson, P.R.F. Bell and M.M. Thompson *Department of Surgery, University of Leicester, Leicester*

Background: Endovascular abdominal aortic aneurysm (AAA) repair has been proposed as a minimally invasive alternative to conventional surgery. This study aimed to quantify the metabolic response in comparative cohorts undergoing both conventional and endovascular aortic surgery.
Method: Forty-three patients were allocated to endovascular or conventional surgery according to aneurysm morphology. All patients received a standard general anaesthetic and had 17 serial blood (venous and mixed venous, via pulmonary artery catheter) and urine samples collected in the perioperative period. Blood samples were immediately centrifuged and plasma snap frozen in liquid nitrogen for later analysis. Samples underwent analysis for the cytokines, interleukin (IL)-1β, tumour necrosis factor-α (TNF-α) and IL-6. White cell and platelet activation were estimated indirectly by measuring L-selectin and myeloperoxidase and thromboxane β2 and 11-dehydrothromboxane β2 (11-dhTx), respectively. Renal injury was assessed by estimation of the albumin/creatinine ratio (A/C) and urinary NAGs. Fibrinogen and D-dimer were calculated to assess activation of the clotting cascade.
Results: Twenty-three patients underwent endovascular AAA repair. Their median age was 72 years (range 60–81 years) and aneurysm size 5·5 (range 4·8–7·3) cm. Twenty had conventional surgery. Their median age

was 67 (range 58–81) years and aneurysm size 5·7 (range 5·0–9·4) cm. All metabolites varied throughout the perioperative period. Results are illustrated as peak median values.

	IL-1β† (pg/ml)	TNF-α† (pg/ml)	IL-6† (pg/ml)	A/C‡ (mg/mmol)	D-Dimer	11-dhTx† (pg/ml)
Conventional	3·4	27·3	217·4	26·4	4500	1291·6
Endovascular	2·6*	11·0*	144·2*	13·2*	1250*	2918·2*

$^*P<0{\cdot}05$

Conclusion: These data suggest the ischaemia reperfusion injury associated with conventional aneurysm repair is largely negated by endovascular techniques. This may be translated to a lower incidence of multiple organ failure after endovascular surgery.

Vascular 045

Outcome for patients with large abdominal aortic aneurysms considered unfit for surgery

A. Jones, D. Cahill and R. Gardham *Chase Farm Hospital, The Ridgeway, Enfield*

Background: This study aimed to determine the risk of rupture in untreated large abdominal aortic aneurysms (AAA) and provide data to assist the decisions to operate, or not, in high-risk patients.
Method: Clinicians were asked to refer all patients found to have an AAA, even if unfit or elderly. In 9 years, 60 of 192 patients with an AAA 5 cm or greater were judged unfit for elective operation. Data were available for 58 non-operated patients with a minimum follow-up of 2 years. Initial AAA diameters at presentation were 5–5·9 cm ($n=25$) and ≥6 cm ($n=33$). Kaplan–Meier survival curves were calculated for both groups.
Results: Of 41 patients aged ≥80 years, 33 (80 per cent) were rejected for operation, compared with only 17 per cent of those patients aged <80 years. The reason for rejection was cardiovascular problems (26), 'old age' (15), malignancy (8), respiratory (6) and patient wishes (3). The mean age of non-operated patients was 80·7 (range 69–93) years. At the end of the study 51 out of 58 non-operated patients had died, with seven still alive. Median survival was 19 (range 1–99) months. The annual risk of rupture for a 5–5·9 cm AAA was 9 per cent, and for ≥6 cm AAA 13 per cent. The median time to rupture was 18 (range 1–38) months. Death from other causes occurred in 29 patients, compared with 19 deaths from rupture and three deaths of uncertain cause, two of them sudden. Three patients had operations for rupture with two deaths and one survivor. For the electively operated group of 132 patients (mean age 73 years) the 30-day mortality was four (3 per cent).
Conclusion: The minimum annual risk of rupture for an AAA >5 cm exceeds the expected operative mortality for fit patients. However, in the unfit group most died of other causes and few would have benefited from elective operation.

Vascular 046

Sac volume following endoluminal repair of aneurysms

M. Dellacorte, W. Lees and M. Adiseshiah *UCL Hospitals Vascular Unit, London*

Background: What happens to the sac after endoluminal repair of an aneurysm remains uncertain. The aim of this study was to assess sac volume in the first 2 years after such repair.
Method: Twenty-eight cases of endoluminal repair of aneurysms, 21 infrarenal abdominal (AAA), three iliac and four popliteal, underwent 3-dimensional reconstruction of their computerized tomographic flow lines and proximal neck diameters over a median period of 11 months (range 6–22 months) were calculated.
Results: The analysis is shown below:

	Total sac volume (ml)	Volume of thrombus (ml)	Flow-line (mm)	Proximal neck diameter (mm)
Preoperative	119 (78–294)	38 (11–124)	86·1 (52·9–112·2)	20·3 (15·6–24·1)
Postoperative 5 days	133 (100–338)	76 (42–258)	80·1 (57·5–115·2)	21·4 (17·0–26·1)
Postoperative >6 months	128 (95–364)	82 (37–270)	89·4 (60·6–123·5)	21·0 (17·8–23·3)
P (Wilcoxon)	ns	Pre vs 5 days <0·05	<0·05	Pre vs 5 days <0·05

The changes in total sac volume became significant ($P<0{\cdot}05$) after two patients with obvious upper stent leaks were excluded. Perigraft flow in three other patients from patent lumbar arteries did not affect volume measurements. The linear changes in the flow line were reflected by similar changes in the vascular channel volumes through the aneurysm. The maximal anteroposterity diameter did not change significantly although the shape of the aneurysm did. Similar results were obtained from the iliac and popliteal aneurysms. There was no change in the distance between the lowest renal and the top of the upper stent over the period of the study.
Conclusion: There was a significant increase in sac volume 5 days after aneurysm exclusion due to an increase in thrombus volume followed by a <5 per cent decrease after 6 months. This was accompanied by an initial shortening of the flow line at 5 days, followed by a 4 per cent increase after a median of 11 months implying lengthening of the graft. Proximal neck diameter initially increased and then did not change, and there was no slippage of the stent-graft.

Vascular 047

Abdominal aortic aneurysm repair in octogenarians

A.S. Atwal, D.M. Baker, P.W. Wenham and B.R. Hopkinson
Queen's Medical Centre, Nottingham

Background: This study aimed to determine perioperative morbidity and mortality in octogenarians undergoing abdominal aortic aneurysm (AAA) repair and to identify the factors that influence early survival.
Method: Retrospective case note review of 77 octogenarians (60 men, 17 women), median age 82 (range 80–91) years undergoing AAA repair between 1979 and 1994. There were 25 elective, 14 symptomatic, and 38 ruptured AAAs in the series. Mean aneurysm diameter was 72 (range 50–120) mm. Forty-one of the 77 patients (53 per cent) had a preoperative history of cardiac, respiratory, renal or cerebrovascular disease. Thirteen (17 per cent) had a history of disease affecting two of these systems.
Results: Overall 30-day mortality in the series was 47 per cent (36 of 77). Thirty-day mortality in the elective group was 20 per cent (5 of 25), in the symptomatic group 36 per cent (5 of 14) and in the ruptured group 68 per cent (26 of 38) ($P<0{\cdot}001$, χ^2 test). Perioperative complications occurred in 50 of 77 (65 per cent) patients. These included pneumonia in 22 (29 per cent), myocardial infarction in 32 (42 per cent), renal failure in 11 (14 per cent) and multi-system organ failure in 6 (8 per cent) patients. Preoperative comorbidity, AAA size and type of graft used for repair did not influence survival. Type of AAA (elective, symptomatic or ruptured) was the only independent predictor of survival in these patients.
Conclusion: Perioperative morbidity and mortality in octogenarians undergoing AAA repair in this series is high, including the elective patient subgroup. Rigorous patient selection is necessary when considering octogenarian patients for AAA repair.

Vascular 048

Centralized vascular surgical services and the community outcome for ruptured abdominal aortic aneurysm

D.J. Adam, I.V. Mohan, W.P. Stuart, M. Bain*, C.V. Ruckley and A.W. Bradbury *Vascular Surgery Unit, University Department of Surgery, Royal Infirmary, Edinburgh and *Information and Statistics Division of the Scottish Health Service*

Background: The aim of this study was to examine the community management of patients with ruptured abdominal aortic aneurysm (AAA) within the catchment area of this regional vascular surgery unit and to examine the relationship between transfer distance and outcome in patients admitted to this unit.
Method: Population data for the catchment area were obtained from the Information and Statistics Division of the National Health Service. Unit data were obtained from a prospectively gathered database. Transfer distance was defined as the road distance between this unit and the patient's residence.
Results: Between 1 January 1989 and 31 December 1995, 972 cases of ruptured AAA were identified. Two hundred and nineteen (23 per cent) patients were certified dead in the community; 372 (38 per cent) patients were admitted to hospital but not transferred to this unit, and of these only 24 were operated and 14 survived. Of the 381 (39 per cent) patients admitted to this unit, overall mortality was 152 of 310 (49 per cent) patients who were admitted directly and 41 of 71 (58 per cent) patients who were transferred from other hospitals. Operated patients ($n = 316$, 83 per cent) travelled significantly further (median 6·9, range <1–39, miles) than 65 (17 per cent) non-operated patients (median 3·1, range <1–36, miles, $P = 0{\cdot}0001$, Mann–Whitney). There was no significant difference in transfer distance between 188 (59 per cent) operated patients who survived (median 5·5, range <1–31, miles) and 128 (41 per cent) who did not (median 5·5, range <1–29, miles $P = 0{\cdot}9$). Overall community survival from ruptured AAA was 202 of 972 (20 per cent).
Conclusion: These data suggest that transferring stable patients with ruptured AAA to a regional vascular unit does not increase operative mortality. Whether the need to transfer patients reduces the proportion who are deemed appropriate for surgical intervention so prejudicing community mortality remains unknown.

Vascular 049

Ruptured abdominal aortic aneurysm is associated with inhibition of systemic fibrinolysis

D.J. Adam, W.P. Stuart, C.A. Ludlam*, C.V. Ruckley and A.W. Bradbury *Vascular Surgery Unit, University Department of Surgery and *Department of Haematology, Royal Infirmary of Edinburgh, Edinburgh*

Background: It has been suggested that ruptured abdominal aortic aneurysm (AAA) is associated with systemic fibrinolysis and that haemorrhage may be limited by anti-fibrinolytic therapy with aprotinin. This study examines systemic fibrinolysis and thrombin generation in patients operated for ruptured and non-ruptured AAA.
Method: Ten patients undergoing emergency repair of ruptured and nine undergoing repair of non-ruptured AAA were studied. Tissue plasminogen activator (t-PA) activity, plasminogen activator inhibitor (PAI) activity, and prothrombin fragment (PF) 1+2 were measured preoperatively, immediately before and 5 min after aortic clamp release, and 24 h postoperatively.
Results: Preoperatively, ruptured AAA was associated with significantly increased PAI activity (median 36·5, range 20·6–38·8 activity units/ml) versus non-rupture (median 8·2, range 3·2–21·7; $P < 0{\cdot}001$, Mann–Whitney) and significantly decreased t-PA activity (median 0·12, range 0·06–0·43 IU/ml) versus non-rupture (median 0·49, range 0·14–3·2; $P < 0{\cdot}01$, Mann–Whitney). In both groups there was a significant increase in PF 1+2 above the normal range (0·4–1·1 nmol/l) but this was significantly greater in patients with rupture (median 9·0, range 5·4–11·6) versus non-rupture (median 2·2, range 0·7–7·1; $P < 0{\cdot}001$, Mann–Whitney). These differences persisted throughout the course of surgery. At 24 h, PAI activity remained above normal for ruptured AAA but was not significantly different from non-rupture; t-PA activity was within the normal range in both groups, and PF 1+2 remained above the normal range in both groups but there was no significant difference between the groups.
Conclusion: Ruptured AAA is associated with systemic thrombin generation and inhibition of systemic fibrinolysis. These data do not support the use of anti-fibrinolytic therapy in patients operated for ruptured AAA.

Vascular 050

Training in abdominal aortic aneurysm surgery

S.M. Evans, D.J. Adam, J.A. Murie, A.McL. Jenkins, C.V. Ruckley and A.W. Bradbury *Vascular Surgery Unit, University Department of Surgery, Royal Infirmary, Edinburgh*

Background: Reduction in working hours and 'Calmanization' of training mean that operative experience must be gained more quickly. This study examines the effect of Calman on training and outcome after abdominal aortic aneurysm (AAA) repair, a nationally agreed vascular 'indicator operation' (Royal College Confidential Enquiry into Surgical Training 1996).
Method: Analysis of a prospectively gathered computerized database of 1116 consecutive AAA repairs performed between 1 January 1987 and 30 September 1997.
Results: Since 1991, supervised trainees have performed a significantly greater proportion of both elective and emergency cases ($P < 0{\cdot}01$, χ^2 test). Overall operative mortality did not differ significantly between the two time periods studied, and within each time period mortality was not significantly related to consultant presence at the operating table (Table).

		1987–1991	1992–1997
Elective	Consultant operating/assisting/not scrubbed (*n*, %) operative mortality (%)	95(73)/26(20)/9(7) 5(5)/3(8)/0	129(55)/79(33)/28(12) 7(5)/7(9)/2(7)
Symptomatic	Consultant operating/assisting/not scrubbed (*n*, %) operative mortality (%)	84(69)/23(19)/14(12) 6(7)/3(13)/1(7)	68(49)/36(26)/35(25) 9(13)/3(8)/3(9)
Rupture	Consultant operating/assisting/not scrubbed (*n*, %) operative mortality (%)	173(76)/36(16)/20(8) 67(39)/10(28)/4(20)	155(59)/47(18)/59(23) 66(43)/12(26)/30(51)

Conclusion: Supervised trainees can perform an increasing proportion of elective and emergency AAA surgery without increasing operative mortality. Towards the end of training, surgical trainees can safely operate 'solo' in selected cases.

Vascular 051

Percutaneous endoluminal grafting for femoropopliteal disease: a feasibility study

M.S. Baguneid, D.J.A. Scott, A. Nevelsteen and M.G. Walker
Department of Vascular Surgery, Manchester Royal Infirmary, Manchester

Background: A feasibility study was carried out to assess the role of a balloon-mounted expanded polytetrafluoroethylene graft with proximal and distal anchoring stents in patients with disabling claudication considered unsuitable for angioplasty because of the severity of the disease.

Method: Thirty-one patients with claudication were considered suitable for treatment. All had significant disease confined to the superficial femoral artery (SFA) and satisfied the entry criteria of two or more vessel run-off and minimum SFA diameter of 4 mm at stent anchor sites. Six were subsequently excluded following intravascular ultrasound interrogation. Procedures were performed under local (21) or general (4) anaesthesia, using a 9F introducer sheath.
Results: Successful deployment of the stent grafts was achieved in 22 cases, with three failures; two failures occurred after encountering difficulties with the introducer sheath and there was one device failure. Of those patients in whom graft deployment was successful, primary patency was achieved in ten (46 per cent) and secondary patency in 14 (64 per cent) at 1 year follow-up.
Conclusion: While initial results with this device have proved disappointing, current development in the design of this stent graft to one that is fully supported may result in this becoming a viable alternative to angioplasty or surgery.

Vascular 052

Colonoscopy with biopsy after aortic surgery: a unique study of the incidence of colonic ischaemia

M. Welch, L. Gurnani, M.S. Baguneid, D. Dodd, M. Bukhari, G.D. Griffiths and M.G. Walker *Department of Vascular Surgery, Manchester Royal Infirmary, Manchester*

Background: Colonic ischaemia is a well-documented complication of abdominal aortic reconstruction. This is the first prospective study in which all patients have had routine pre- and postoperative colonoscopy and biopsy, in order to determine the true incidence and implications.
Method: Fifty-six patients undergoing elective infrarenal aortic surgery, 28 for aneurysm and 28 for occlusive disease, were colonoscoped and biopsied preoperatively and 1 week postoperatively.
Results: All patients had normal macroscopic and microscopic appearances on preoperative biopsies. A 30 per cent incidence of postoperative colonic ischaemia was identified by histology (16 of 53 patients), almost half of these (7 of 16) having normal macroscopic appearances. Two factors exhibited a statistically significant association with the development of ischaemia: prolonged cross-clamp time (mean of 44·75 versus 35 min, $P<0·05$, Mann–Whitney U test) and postoperative diarrhoea (88 per cent versus 13 per cent, $P<0·001$, Fischer's exact test). Co-morbidity was much higher in those patients with ischaemia (81 per cent versus 13 per cent, $P<0·005$, Fisher's exact test). Overall morbidity was significantly greater in the aneurysm group (46 per cent versus 21 per cent, $P<0·05$, Fisher's exact test).
Conclusion: Colonic ischaemia after aortic reconstruction is a much more commoner occurrence than previously reported and, although mild and transient in many cases, is still associated with significant morbidity. When suspected, colonoscopy with biopsy is recommended.

Vascular 053

Intravenous clot versus thrombus: serious implications of conclusions drawn from studies using models of 'thrombosis'

C.L. McGuinness, J. Humphries, A. Smith and K.G. Burnand
Department of Surgery, St Thomas' Hospital, London

Background: Many models of thrombosis exist but adequate characterization of the coagulum produced has often not been performed. In some models, isolated venous segments have been used and in others, blood flow is completely stopped which by definition may not result in true thrombus formation. This study aimed to determine whether the histological and electron microscopic appearances of human venous thrombus, experimental intravascular 'thrombus' formed in isolated vein segments, experimental thrombus formed in flowing blood and *ex vivo* clot are similar in structure and composition.
Method: Two rat models of thrombosis were used. One model used diminished flow only. The other used an isolated segment with no flow. Human thrombi were obtained from deep veins in amputation specimens and superficial veins from varicose vein operations. Human and rat clots were formed from peripheral blood. Paraffin sections were stained with Martius Scarlet Blue, haematoxylin and eosin, and immunocytochemical stains for leucocytes, platelets, fibrin and monocytes. Specimens for electron microscopy were either perfuse-fixed or post-fixed in glutaraldehyde.
Results: Human thrombus had an organized structure comprised of alternate layers of platelet/fibrin and red cells. White cells lined up along these layers. The thrombus from the rat model using low flow only was identical to human thrombi. The *ex vivo* clots were similar to each other, being comprised almost exclusively of red cells with randomly distributed white cells and very few platelets. Fibrin was present only as clumps. Thrombi from the no-flow model closely resembled the *ex vivo* clots. Scanning electron micrographs revealed that the colts and 'thrombi' produced in no-flow segments consisted largely of red cells trapped within a loose mesh of fibrin. Platelets were more abundant in human thrombus and the low-flow model.
Conclusion: Thrombus produced in a model where flow is reduced, without complete occlusion, is similar to human thrombus but both are markedly different in structural formation from *ex vivo* clots and the coagulum produced by some thrombosis models. Resolution of these different tissues, therefore, may also be dissimilar and thus, conclusions drawn about the effectiveness of substances intended to inhibit thrombogenesis or accelerate thrombolysis may be invalid when experimental models using cessation of flow are employed.

Vascular 054

Outcome following abdominal aortic aneurysm surgery in a district general hospital

I.C. Chetter, K.F. Chin, N.K. Sharma, J. Thompson and V.K. Modgill *Department of Surgery, Halifax Royal Infirmary, Halifax*

Background: The aim of this study was to assess the survival of patients undergoing elective and emergency abdominal aortic aneurysm (AAA) surgery in a district general hospital.
Method: A retrospective review of accident and emergency, operating theatre, intensive care unit and ward documentation revealed that, from 1 January 1986 to 31 March 1997, 118 patients underwent AAA surgery in this hospital. Individual patient details were obtained from the case notes. Fifty-two patients underwent elective repair: 42 men and 10 women of median age 70 (range 52–82) years. Sixty-six patients underwent emergency repair; 58 men and eight women of median age 70 (range 45–85) years.
Results:

Interval (months)	No. patients at risk at start	Patients withdrawn due to: Duration	LFU	Death	Interval survival	Cumulative survival (%)	Standard error (%)
0–1	*52* **66**	*0* **0**	*0* **0**	*1* **19**	*0·98* **0·71**	*100* **100**	*0* **0**
1–3	*51* **47**	*0* **0**	*1* **6**	*0* **7**	*0·98* **0·98**	*98* **71**	*1·94* **5·58**
3–12	*50* **40**	*9* **7**	*2* **2**	*1* **4**	*0·98* **0·97**	*96* **70**	*2·27* **6·06**
12–24	*38* **27**	*3* **1**	*5* **3**	*0* **7**	*1·00* **0·72**	*94* **68**	*3·74* **7·40**
24–48	*30* **16**	*1* **1**	*2* **2**	*2* **6**	*0·96* **0·59**	*94* **49**	*4·20* **8·75**
48–60	*25* **7**	*7* **1**	*5* **0**	*1* **0**	*0·95* **1·00**	*90* **29**	*5·69* **9·24**
60–72	*12* **6**	*4* **3**	*0* **0**	*1* **1**	*0·90* **0·75**	*86* **29**	*9·29* **9·98**
72–84	*7* **5**	*2* **0**	*0* **0**	*3* **1**	*0·50* **0·80**	*77* **22**	*13·96* **8·69**

Emergency AAA in **bold**, elective AAA in *italics*. LFU = lost to follow-up.

Conclusion: Acceptable 30-day mortality can be obtained in a district general hospital for both elective and emergency AAA repair. Long-term survival following emergency surgery is much lower than that for elective, and this may have implications regarding AAA screening.

Vascular 055

An audit of varicose vein surgery: the patient's perspective and the reasons for dissatisfaction

H. Jones, M. Ahmad, A. Raznahan, W. Sherwood and J. Derodra
Mayday University Hospital, Thornton Heath, Surrey

Background: Variscose veins (VVs) are common and constitute a significant workload in surgical practice. We have tried to elicit patient satisfaction after VV surgery and to determine the causes of dissatisfaction.
Method: A questionnaire was sent to 404 patients who had undergone VV surgery over a 2-year period, requesting information about symptoms before and after surgery, postoperative complications and satisfaction following operation. These results were correlated with information obtained from theatre registers and patient case notes.
Results: Three hundred and thirty-five patients responded. The main symptoms were aching (59 per cent), itching (33 per cent), acute pain (24 per cent) and ulcers (7 per cent). Postoperative complications were reported by 36 per cent (bruising 58 per cent, infection 26 per cent, bleeding 18 per cent, others 23 per cent). Seventy-nine per cent were satisfied with the outcome of surgery and 88 per cent noted an improvement in symptoms. Ninety-five per cent were satisfied with the preoperative explanation. The main factors associated with dissatisfaction were being female (24 per cent versus 11 per cent; $P<0{\cdot}025$), bilateral surgery (32 per cent; $P<0{\cdot}02$), junior staff performing the operation (31 per cent versus 18 per cent; $P<0{\cdot}025$), postoperative complications (29 per cent; $P<0{\cdot}005$), no improvement in symptoms (75 per cent; $P<0{\cdot}005$) and dissatisfaction with preoperative explanation (61 per cent; $P<0{\cdot}0005$). Although dissatisfied with the results of surgery, 57 per cent reported an improvement in symptoms. Of the 69 non-responders, 41 were reviewed in the out-patient clinic and 85 per cent were satisfied.
Conclusion: The vast majority of patients were satisfied and benefitted from the VV operation. Satisfaction rates may be further improved by ensuring that the patient is fully informed about the operation and its limitations, and that junior staff are better trained and supervised in operating on VVs.

Immunohistochemical expression of Desmoglein 2 and E-cadherin in breast carcinomas relative to other known prognostic factors

E.L. Davies, J.M. Gee*, R.A. Cochrane, A. Sharma, R. Nicholson*, W.G. Jiang and R.E. Mansel *Department of Surgery and *Tenovus Research Centre, University Hospital of Wales, Heath Park, Cardiff*

Background: This study aimed to compare the relative immunohistochemical (IHC) staining of two cell–cell adhesion molecules, Desmoglein 2 (Dsg2) and E-cadherin (E-cad), in breast cancer and normal breast tissue. Correlation of this staining with several known clinical and IHC prognostic factors was also studied.
Method: Frozen tissue from 52 ductal, 11 lobular, three ductal carcinomas *in situ* (DCIS), 11 tumour-associated normal (TAN) and nine normal breast tissues were IHC stained using Dsg2 and E-cad monoclonal antibodies.
Results: Both antibodies demonstrated membranous staining in the majority of carcinomas (98 per cent versus 80 per cent, Dsg2 versus E-cad, respectively). Significantly stronger IHC staining was seen in normal compared to carcinoma ($P<0.0001$) with both antibodies, and between DCIS and carcinoma ($P=0.02$ and $P=0.07$, E-cad versus Dsg2, respectively). There was an inverse correlation in IHC staining and size of the primary tumour which reached significance with E-cad ($P=0.04$ versus $P=0.07$, E-cad versus Dsg2, Mann–Whitney U-test). E-cad showed an inverse correlation with grade of ductal tumour ($P=0.04$, Grade 1 demonstrating strong membranous staining versus Grade 2 and 3). There was a trend for lobular carcinomas to stain weakly with both antibodies when compared with the ductals and this was significant with E-cad ($P=0.004$ versus $P=0.059$, E-cad versus Dsg2, respectively) No relationship was seen with lymph node status or any of the remaining prognostic factors examined.
Conclusion: We have demonstrated that Dsg2 and E-cadherin are present in breast cancer tissue and that both cell–cell adhesion molecules may be important in the local progression of breast cancer

Poster 002

Prognostic significance of CD44s and CD44v6 in breast cancer, an immunohistological study

S.F. Morris, D.M. O'Hanlon, T McHale†, G.E Connolly† and H.F. Given *National Breast Cancer Research Institute (NBCRI), Department of Surgery, and †Department of Pathology, University College Hospital Galway, Newcastle, Galway, Ireland*

Background: A number of studies *in vitro* and *in vivo* have associated the expression of the v6 variant isoform of CD44 with an increased incidence of metastasis We examined the prognostic significance of CD44v6 in a group of 109 women with stage 2 breast cancer
Method: This study, using immunohistochemical techniques, examined the prognostic significance of CD44s and CD44v6 expression in a cohort of 109 women with a median follow-up of 50 months, presenting with stage 2 breast cancer
Results: CD44v6 expression in tissue sections was found to be independent of patient age, tumour size and grade, and lymph node status. Neither was any correlation established between CD44v6 expression, and serum levels of Ca153 both pre- and postoperatively, BCL2, nm23, p53, P cadherin, or oestrogen receptor status. Similar findings were observed for CD44s. A significant correlation was observed between expression of CD44s and CD44v6 ($P<0.05$ χ^2). Overall and disease-free survival were both found to be independent of expression of CD44s and/or CD44v6
Conclusion: In conclusion, CD44s and CD44v6 expression did not correlate with established prognostic indicators, disease-free survival, overall survival, or tumour differentiation

Poster 003

MRI in the detection of breast cancer multicentricity

M. Douek[1], J. Vaidya[1], S.R. Lakhani[2], K. Blanchard[3], M.A. Hall-Cragg[3], T. Davidson[1], M. Baum[1] and I. Taylor[1] *Departments of [1]Surgery, [2]Histopathology and [3]Radiology, University College London Medical School, London*

Background: Whilst mammograms rely on microcalcifications for detecting cancers, contrast-enhanced magnetic resonance imaging (MRI) relies on vascularity and vascular permeability. In this study we compared the preoperative detection of multicentric foci (MCF) by contrast-enhanced MRI with standard radiological-histological examination of resected specimens (modified Egan's method).
Method: Ten patients with newly diagnosed breast cancer underwent preoperative contrast-enhanced breast MRI using a transverse T1-weighted three-dimensional (3D) FLASH sequence. After surgical excision the specimens were fixed and cut in the same plane as the MRI. The pathologist sampled any identifiable lesion for histological analysis and subsequently a radiograph was performed on the specimen slices Two observers identified calcifications away from the primary tumour and these were then sampled and paraffin blocked. One section was cut from each block, stained and examined by microscopy The remaining blocks were X-rayed and further sections were taken if calcifications were identified. MRI images were reviewed independently and findings compared with histology.
Results: On radiography of tumour slices, 71 suspicious areas were identified and sampled Out of these, 15 areas of DCIS or invasive cancer were identified in five patients On MRI, 19 enhancing foci were identified in seven patients. All five patients with histologically proven malignant areas had some enhancing foci on MRI Two tumours showed diffuse patchy enhancement and in these all 11 areas sampled showed either DCIS or frank invasive disease MRI could potentially detect 14/15 histologically proven MCF (false positive = 1) but detected four additional enhancing foci (false positive = 4).
Conclusion: Our findings suggest that MRI is highly sensitive for the detection of MCF invasive or *in situ* tumours but that the specificity for the diagnosis of malignant change in these foci may be low MRI could be used to investigate the clinical significance of unresected MCF in a future prospective study

Poster 004

Sentinel lymph node biopsy in breast cancer: prospective assessment of two complementary techniques

S. Chattopadhay, P.J. Drew, T. Davis*, J.R.T. Monson and M.J. Kerin *The University of Hull Academic Surgical Unit, Castle Hill Hospital and *Department of Nuclear Medicine, Princess Royal Hospital, Hull*

Background: Axillary lymph node dissection is a necessary staging procedure in breast cancer but is associated with potentially avoidable morbidity in patients with node-negative disease. The aim of this study is to assess two complementary methods of sentinel node assessment in patients with early breast cancer.
Method: Sentinel node localization was performed using 45 mbi of tech-

netium-labelled sulphacolloid injected subdermally close to the tumour 4–6 h prior to surgery. All patients underwent lymphoscintigraphy prior to surgery. In addition 1·5 ml of patent blue dye was injected peritumourally at the time of surgery following the induction of anaesthesia and prior to skin preparation. An axillary clearance was then performed after location of the sentinel node by a combination of direct visual identification of blue dye and directional gamma detector (Neoprobe, Autosuture, UK).
Results: A consecutive initial series of 15 patients have been recruited for the study. The sentinel node (node with the highest level of counts or concentration of blue dye) was successfully identified in all cases by the Neoprobe and was visibly blue in 10 of the 15 patients. Five patients had node-positive disease and in all five the sentinel node was positive (in three it was the only positive node). Blue dye identified the positive node in three of the five cases.
Conclusion: These preliminary results demonstrate that the two techniques are complementary but the Neoprobe appears to be the more sensitive technique. Application of this technique should facilitate the utilization of less radical axillary surgery in the majority of patients with early breast cancer.

Poster 005

Assessment of mammographic abnormalities with the Advanced Breast Biopsy Instrumentation system

M. Menon, P.J. Drew, K. Heer, M.J. Imrie, J.N. Fox,
P.J. Carleton, J.R.T. Monson and M.J. Kerin *The University of Hull Academic Surgical Unit, Castle Hill Hospital, Hull*

Background: The drawbacks of breast screening include unnecessary intervention in patients with benign disease and lack of preoperative diagnosis in patients with screen-detected malignancy. We are prospectively assessing the impact of the Advanced Breast Biopsy Instrumentation (ABBI) system (Autosuture U.K.) which allows stereotactic biopsy and excision of screen-detected lesions.
Method: Patients with screen-detected clinically occult abnormalities were referred for evaluation on the ABBI system. All procedures were carried out under local anaesthetic. All data including a patient satisfaction questionnaire were collected prospectively by a dedicated research nurse.
Results: To date, 78 patients have undergone 20 excision biopsies and 58 core biopsies. Of the excision biopsies, 10 were malignant: six invasive ductal, four ductal carcinoma *in situ*, and the remaining benign lesions included radial scars ($n = 2$), complex sclerosing lesions ($n = 2$) and fibroadenomata. Mean duration of the excision biopsies was 50 (range 30–105) min. Histology of the core biopsies revealed malignancy in 12 cases and benign disease in 46. The procedures were well tolerated by all patients with no complications.
Conclusion: The ABBI system provides a well-tolerated accurate diagnostic intervention for patients with screen-detected breast lesions. It facilitates accurate preoperative diagnosis and has the potential for therapeutic applications in patients with very small radiologically detected cancers.

Poster 006

Will routine breast screening improve mortality?

D.B. Kingsmore, A. Ssemwogerere†, D. Hole†, C.R. Gillis† and W.D. George *Department of Surgery, Western Infirmary, and †West of Scotland Cancer Surveillance Unit, Ruchill Hospital, Glasgow*

Background: Screening mammography aims to detect disease at an earlier stage in the belief that earlier surgery will cure more women. We analyse the impact of the NHS screening programme on disease stage and incidence rates, and provide an assessement of whether the desired reduction in mortality is likely to be achieved.
Method: All cases of invasive breast cancer from 1982 to 1996 in women under 75 who lived in a defined geographical area served by two screening centres were identified and the pathology reports obtained. The incidence rates for the second round were adjusted to pre-screening levels and the 7-year mortality estimated.
Results: A significant stage migration was seen and more crucially a reduction in the incidence of large tumours (Table). Our estimate of the 7-year mortality reduction due to screening was approximately 20 per cent.

Table: the incidence of breast cancer in women aged 50–64 by screening round and the expected mortality benefits.

Tumour size	7-year mortality	Incidence pre-screening (per 100 000)	Adjusted incidence interval round	Mortality rate pre-screening (per 100 000)	Estimated mortality by first interval	Estimated benefit
<20 mm	17%	36·8	78·2	6·3	13·3	–7·0
20–39 mm	36%	55·0	39·7	19·8	14·3	5·5
>40 mm	55%	22·7	10·6	12·5	5·8	6·2
Not stated	45%	38·2	24·4	17·2	11·0	17·2
Total		152·7	152·9	55·8	44·4	12·85

Conclusion: The NHS Breast Screening Programme has lowered the incidence of large tumours. This decrease should translate into a 20 per cent reduction in mortality in the next few years.

Poster 007

Definitive axillary treatment and survival of node-positive women with breast cancer

D.B. Kingsmore, D. Hole†, C.R. Gillis† and W.D. George
Department of Surgery, Western Infirmary, and †Cancer Surveillance Unit, Ruchill Hospital, Glasgow

Background: There remains much debate on the necessity and extent of axillary dissection in the surgical management of breast cancer and whether axillary recurrence is associated with a poorer overall survival. The aim of this study is to investigate the impact of inadequate definitive treatment of the axilla, with either surgical clearance or radiotherapy on the survival of node-positive women.
Method: A total of 7144 women with histologically confirmed invasive breast cancers, aged <75 years, who lived in a defined geographical area (population 1·5 million) were identified through the cancer registry between 1980 and 1994. Details of treatment were derived from case records and pathology reports. Cause of death was derived from death certificate data.
Results: Four hundred and eighteen node-positive women had less than four nodes sampled. These women had a significantly poorer survival compared to women with four or more nodes sampled, $P = 0·0017$ (see Table). On reviewing the case-notes of the women with less than four nodes removed only 14 per cent (5/36) were referred for radiotherapy in 1980 but this had risen to 65 per cent (22/34) by 1992–1994.

Table: the 5- and 10-year survival and relative hazard ratio (RHR) of node-positive women by sample size.

	Axillary node sample size	
	<4 nodes	>4 nodes
Number of patients	418	1809
5-year survival	53	59
10-year survival	34	42
RHR*	1·26 (1·092–1·464)	1·0

*RHR: The relative hazard ratio adjusted for tumour size

Conclusion: Adequate axillary treatment remains necessary for regional disease control and survival. The majority of node-positive women with less than four nodes removed were not referred for radiotherapy and this may have contributed to the poorer survival of these patients.

Poster 008

The value of potential markers of angiogenesis in breast cancer

G.J. Byrne, J. Iddon, R. Aggarwal, G. Sinha, A. Howell and N.J. Bundred *University Hospital of South Manchester, Manchester*

Background: Production of the potent endothelial cell mitogen vascular endothelial growth factor (VEGF) correlates, in breast cancer cytosols, with development of angiogenesis (assessed by microvessel density) and induces vascular cell adhesion molecule (VCAM) expression in endothelial cells. The aim of this study was to assess the value of serum VCAM and VEGF in predicting tumour angiogenesis and metastasis as well as assessing response to therapy.
Method: Serum levels of soluble VCAM and VEGF were measured in women with early breast cancer (EBC) ($n=93$) and women with progressing advanced breast cancer (ABC) ($n=24$) using ELISA (R&D Systems Ltd., Oxon, UK). Serum measurements were compared to known histological prognostic parameters and to microvessel density by immunostaining tumours with the CD31 antigen.
Results: In EBC serum levels of VCAM (mean 769·5, range 263–1387, ng/ml) were higher than both pre- and postmenopausal controls (483 ng/ml and 478 ng/ml, $P<0·001$ and $P<0·01$, respectively). Levels of serum VEGF in EBC (mean 299 ng/ml, range 47·1–1321) were raised only when compared to postmenopausal women (mean 246, range 66·5– 621·5, ng/ml) ($P<0·05$). Levels of serum VCAM, but not VEGF, correlated with microvessel density ($r=0·66$, $P<0·001$). Serum VCAM, but not VEGF, was raised in women with ABC (mean 1236, range 349–3914) when compared to EBC ($P<0·001$) and normal controls.
Conclusion: Serum VCAM is a sensitive marker of angiogenesis in breast cancer that could be used to assess responses to therapy in women with ABC and may have prognostic value in EBC. Measurement of serum VEGF levels does not provide diagnostic or prognostically valuable clinical information.

Poster 009

Body mass index, height and cumulative menstrual cycles are not risk factors for poor outcome in breast cancer

K.V. Menon, A. Hodge, J. Houghton and T. Bates *The Breast Unit, The William Harvey Hospital, Ashford, Kent*

Background: The aim of this study was to determine whether body mass index, height and cumulative menstrual cycles are independent prognostic factors following the diagnosis of primary breast cancer.
Method: The body mass index (BMI), height and cumulative menstrual years were calculated at the time of diagnosis for 448 women with primary breast cancer. The effect of BMI, height and cumulative menstrual years on survival time and disease-free interval was estimated by fitting a Cox regression model in each case with all three variables as continuous covariates (significance assessed by likelihood ratio tests).
Results: BMI and height were calculated for $n=403$ patients and cumulative menstrual cycles in $n=388$; there was no effect of BMI on survival time ($P=0·99$; hazard ratio = 1000 [95 per cent confidence interval {CI} range 0·968–1·034]) or disease-free interval ($P=0·92$; hazard ratio = 1·002 [95 per cent CI, range 0·973–1·031]). Height did not affect survival ($P=0·11$; hazard ratio = 0·137 [95 per cent CI, range 0·012–1·5 4]) or disease-free interval ($P=0·13$; hazard ratio = 0·180 [95 per cent CI, range 0·020–1·604]). Similarly, cumulative menstrual cycles did not influence survival ($P=0·74$; hazard ratio = 0·994 [95 per cent CI, range 0·961–1·028]) or disease-free interval ($P=0·34$; hazard ratio = 0·985 [95 per cent CI, range 0·955–1·016]).
Conclusion: The present study found no association between BMI, height and cumulative menstrual cycles on survival time or disease-free interval in patients with primary breast cancer.

Poster 010

Fish-tail plasty as a method of treating post-mastectomy dog-ear

J.C. Doughty and W.D. George *University Department of Surgery, Western Infirmary, Glasgow*

Background: Dog-ear at the lateral end of a mastectomy wound is a common problem, especially in obese patients where mastectomy frequently leaves behind excess skin at the lower border of the axilla. Although an apparently minor problem it often causes the patient great discomfort, the fold of skin rubbing against or overhanging the side panel of the bra. As there is a large fold of skin in this area simply excising the dog-ear may result in an inability to close the wound or may produce a dog-ear more posteriorly. We describe a simple technique for excising this fold at the time of mastectomy or as a secondary procedure.
Method: Under general anaesthetic the patient is positioned on her side with the arm on the affected side placed above her head. A W–Y plasty is performed; the skin is marked in the shape of a 'fish-tail' and the 'fish-tail' excised with either knife or diathermy; caution is taken not to undermine and remove fat from the triangle of skin left behind. The resulting Y is then sutured using 3·0 vicryl. We have treated 20 patients using this technique, five as a primary procedure during mastectomy and 15 as a secondary procedure.
Results: In all 20 patients we have prevented or eliminated the dog-ear at the lateral end of the mastectomy wound. One obese patient developed a wound infection when the procedure was performed as part of the mastectomy but there have been no other complications and all patients have been extremely satisfied with the result.
Conclusion: We conclude that the 'fish-tail' plasty is a successful method of treating post-mastectomy dog-ear as either a primary or secondary procedure.

Poster 011

Tumour bed positivity in women undergoing breast-conserving surgery for primary breast cancer

H.Z. Malik, A.D. Purushotham, R.D. Macmillan, E.A. Mallon[1], A.N. Harnett[2] and W.D. George *University Departments of Surgery and [1]Pathology, and [2]Beatson Oncology Centre, Western Infirmary, Glasgow*

Background: Local recurrence after breast-conserving surgery is associated with a short distant disease-free survival. Early local recurrence is caused by residual disease left behind at the time of initial surgery. The aims of this study were to define the incidence of incomplete excision by using a simple method of assessing residual disease in the tumour bed and to correlate tumour bed positivity with clinico-pathological variables and outcome measures.
Method: A total of 533 women with primary operable breast cancer entered the study between January 1988 and December 1995. Following wide local excision, a 'shaving' of the residual cavity wall was obtained and sent separately for histopathology. These were blocked extensively and sectioned serially and the type and extent of disease assessed. A total of 466 patients (86 per cent) underwent axillary clearance, 129 (28 per cent) of whom were node positive. In all, 398 (75 per cent) received adjuvant radiotherapy to the breast, 63 (12 per cent) chemotherapy and 424 (80 per cent) Tamoxifen.
Results: One hundred and ninety-four patients (36 per cent) had disease (*in situ* or invasive) in the tumour bed. Based on tumour bed positivity, 137 patients (26 per cent overall) either had a further re-excision or mastectomy. The mean follow-up was 6·1 years (range 1·1–8·8 years). Tumour bed positivity was significantly associated with younger age, smaller lumpectomy diameter, Bloom and Richardson grade II, lymph node positivity and the presence of lymphovascular invasion or extensive ductal carcinoma *in situ*. Tumour bed positivity was an independent predictor of systemic recurrence and breast cancer-related death. The local recurrence rate was 2 per cent, systemic recurrence rate 9 per cent and breast cancer-related death rate 7 per cent.

Conclusion: Tumour bed assessment by analysing a shaving of the residual cavity is a simple method of identifying residual disease and by adopting a selective re-excision policy, a low local recurrence rate can be achieved. Tumour bed positivity also appears to predict for systemic recurrence and poorer survival.

Poster 012

Intraoperative frozen section of axillary nodes: a study of its accuracy

J.M. Dixon, U. Mamman and J. Thomas *Edinburgh Breast Unit, Western General Hospital, Edinburgh*

Background: The aim of this study was to assess the role of intraoperative frozen section.
Method: A selected group of 88 patients who either had a low probability of axillary node involvement or where attempts were being made to avoid an axillary clearance. All had a four-node axillary node sampling procedure and the four nodes assessed by frozen section.
Results: The results are shown in the Table. Three hundred and sixty nodes were examined by frozen section.

		Final histology	
	No. patients	Nodes positive	Nodes negative
Patients with negative nodes on frozen section	69	7	62
Patients with positive nodes on frozen section	26	26	0

Sensitivity = 73 per cent, negative predictive value = 90 per cent.

Conclusion: This study showed 10 per cent of patients whose nodes are negative on frozen section have involved nodes on paraffin section. Frozen section of node sampling or sentinel node biopsies has a significant failure rate.

Poster 013

Angiotensin receptor expression and prognostic significance in breast cancer

A.J. Ogedegbe, R. Inwang, J. Puddefoot[*], G.P. Vinson[*] and R. Carpenter *Breast Unit, St Bartholomew's Hospital, West Smithfield, London and* [*]*Department of Biochemistry, Queen Mary and Westfield College, London*

Background: Angiotensin II (AII) is a biologically active peptide of the renin angiotensin system. Most of the known physiological actions of AII are mediated via its type I (ATI) receptor. AII regulates growth and development of tissues and thus may be an important factor in tumour progression. Using a specific monoclonal antibody we have previously shown ATI receptor expression in breast tissue. The aim of this study was to extend our data and relate the expression of ATI receptor to disease progression and to determine quantitatively its relationship to factors known to have prognostic significance in breast cancer.
Method: Formalin-fixed paraffin-embedded breast tissue sections from 151 women, aged between 22 and 84 years were examined by immunocytochemistry using the 6313G2 monoclonal antibody to the ATI receptor. A semi-quantitative staining intensity index (SII) was used to determine the level of expression of the ATI receptor.
Results: Breast tissue from 151 patients were examined, breast cancers $n=102$ (67·5 per cent), benign breast disease $n=47$ (32·5 per cent). Of the breast cancers 37 (36·3 per cent) patients had metastatic axillary lymph node involvement. Semi-quantitative analysis of the ATI receptor expression by SII revealed a range of 0·25–2·25. The mean score for receptor expression was higher in benign as compared to malignant breast tissue, but this difference did not reach significance ($P<0{\cdot}06$). Analysis of the receptor expression in breast cancer showed no relationship with tumour grade but was shown to be significantly correlated with lymph node involvement ($P<0{\cdot}03$).
Conclusion: The expression of ATI receptor appears to be higher in benign as compared to malignant breast tissue. Patients with axillary nodal involvement show a reduction in receptor expression compared to node-negative patients, suggesting AII may be involved in breast cancer metastasis.

Poster 014

Beware the clear margin after breast conserving surgery

T. Usman, M. Stephens and R.M. Kirby *North Staffordshire District General Hospital, Staffordshire*

Background: This study aimed to assess the role of cavity biopsies in assessing the adequacy of clearance after a wide local excision (WLE) for breast carcinoma.
Method: Data were collected prospectively over a 6-year period. Patients undergoing a WLE for invasive cancer ($n=153$), with ductal carcinoma *in situ* (DCIS) ($n=91$) and without DCIS ($n=62$) had biopsies taken from the superior, inferior, medial and lateral flaps together with a deep fascial biopsy. WLE specimens were inked and the margins examined rigorously by the orange peel method. Cavity biopsies were examined in their entirety.
Results:

	Margins clear	Margins involved
Cavity clear	65 (57)	11 (2)
Cavity involved	10 (1)	5 (2)

Figures in brackets are of tumours not associated with DCIS.

When the main specimen contained DCIS 10 per cent of cases had a clear margin with an involved cavity compared to 3 per cent without DCIS ($\chi^2=10{\cdot}28$, $0{\cdot}02>P>0{\cdot}01$).
Conclusion: There is a significantly greater chance of residual disease if invasive tumour is associated with DCIS, and cavity biopsies should not be used in isolation to assess clearance.

Poster 015

Can colour Doppler ultrasonography influence decision on surgical management of the axilla in breast cancer patients?

A. Choy, L. Chagla, R. Lea and D. Cade *Department of Surgery, Leighton Hospital, Crewe, Cheshire*

Background: Axillary dissection is essential in the treatment of breast cancer patients but up to 70 per cent of patients will be negative for nodal metastases and at present no methods are totally accurate for preoperative assessment of nodal status to avoid unnecessary morbidity associated with axillary surgery. Axillary lymph node imaging by colour Doppler ultrasonography (CDU) has a reported accuracy of up to 86·4 per cent and may allow a more appropriate selection of patients for either axillary sampling or clearance.
Method: We have studied a total of 123 patients prospectively and the breast and axilla were scanned with CDU before surgery (age range 26–82 years). One hundred and twenty had unilateral operable breast cancer, two had bilateral cancers and three had axillary recurrences. Patients with large tumours (T3 and T4), clinically involved axillary nodes or positive flow signal on CDU were selected for axillary clearance. All other patients had level 1 axillary sampling.
Results: CDU has a sensitivity of 68 per cent, specificity of 85·33 per cent and positive predictive value of 75·56 per cent. Out of 50 patients with involved nodes 16 had false-negative axillary scans and were treated with radiotherapy to the axilla following axillary sampling. Eleven out of

75 patients with negative nodal metastasis had false-positive scans and underwent axillary clearance, but 85·33 per cent (64/75) of these node-negative patients avoided axillary clearance.
Conclusion: This study demonstrated that CDU is a useful staging tool in breast cancer patients and may aid selection of patients for more appropriate axillary surgery and influence surgical management.

Poster 016

The effect of hormone replacement therapy on screen-detected breast cancers

J. Iddon, C. Harding, C.R.M. Boggis, A.D. Baildam, L. Barr and N.J. Bundred *University Hospital of South Manchester, Manchester*

Background: Hormone replacement therapy (HRT) has been shown to increase the risk of developing breast cancer but cancers developing on HRT are said to have a lower grade and better prognosis. The aims of this study were to determine the effect of HRT on the prognostic factors of cancers detected at the incident screening round and compare these to tumours detected at the prevalent round.
Method: Tumour grade and size, lymph node status, presence of carcinoma *in situ* and history of HRT use were collected from patients with screen-detected cancers, 253 incident and 325 prevalent.
Results: HRT use was similar in prevalent (28·2 per cent) and incidence (28·9 per cent) groups.

	Grade 1		Grade 2		Grade 3	
	HRT	No HRT	HRT	No HRT	HRT	No HRT
Prevalent	30(40·5%)	51(20·0%)	34(45·9%)	166(65·6%)	10(13·5%)	36(14·2%)
All incidents	23(32·5%)	35(19·4%)	45(57·5%)	98(54·4%)	7(9·6%)	40(22·2%)
In situ cancer	11(47·8%)	13(37·1%)	22(52·3%)	33(33·7%)	1(14·3%)	16(40%)

Women who took HRT had more grade 1 tumours ($P=0·001$) detected at the prevalent round. This difference was reduced by the incident round ($P=0·1$) but these women developed fewer grade 3 tumours ($P=0·02$). Women who developed grade 3 tumours in the incident screen were found to have taken HRT for less time (mean 36·5 months [range 8–60]) than those with grade 2 (97·1 months [3–189]) or grade 1 tumours (150·5 months [8–158]). Carcinoma *in situ* occurred in more women taking HRT than those not (36/73 vs 63/180 $P=0·05$). No significant difference in nodal status was found.
Conclusion: Women taking HRT are less likely to develop high-grade tumours and more likely to develop an *in situ* lesion.

Parathyroidectomy for renal hyperparathyroidism: the transplant surgeon's perspective

G. Morris-Stiff, D.J. Bowrey, R. Lord and W.A. Jurewicz
Department of Transplant Surgery, University Hospital of Wales NHS Trust, Heath Park, Cardiff

Background: Up to 10 per cent of patients receiving renal replacement therapy will require parathyroidectomy for secondary hyperparathyroidism. The aim of the current study was to report the management of this condition by a regional transplant unit.
Method: Between November 1994 and September 1997, 34 patients underwent parathyroidectomy for secondary hyperparathyroidism. The study population consisted of 20 male and 14 female patients of median age 41 (range 10–63) years. Renal replacement therapy was as follows: transplant ($n=17$), haemodialysis ($n=10$) and peritoneal dialysis ($n=5$). Two patients were pre-dialysis. Twenty-seven patients underwent subtotal parathyroidectomy and seven patients had a total parathyroidectomy with re-implantation.
Results:

	Preoperative median (IQR)	Postoperative median (IQR)	Statistical significance
Calcium (mmol/l)	3·03 (2·86–3·25)	2·39 (2·19–2·52)	$P<0·05$
Parathormone (pmol/l)	133 (99–150)	3·4 (0·9–11·1)	$P<0·05$
Alkaline phosphatase (IU/ml)	181 (121–237)	103 (63–152)	$P<0·05$
Symptoms: bone pain (%)	17 (50%)	2 (6%)	$P<0·05$
pruritus (%)	9 (26%)	2 (6%)	$P<0·05$

At a median follow-up time of 12 (range 1–33) months all patients are normolcacaemic. All patients with functioning grafts have normal parathyroid hormone (PTH) levels, however, six on haemodialysis have mildly elevated PTH (0 per cent versus 35 per cent, $P<0·05$).
Conclusion: Parathyroidectomy is effective in correcting the calcium biochemistry dysfunction seen in patients with chronic renal failure. Patients with renal transplants have a superior outcome compared to those on dialysis.

Impaired wound healing in patients with HIV infection and AIDS determined by biomechanical strength

P.A. Davis, D.J. Corless, S.G. Appleton and C. Wastell
Department of Academic Surgery, Imperial College School of Medicine, Chelsea and Westminster Hospital, London

Background: Patients with HIV infection and AIDS with low CD4 counts, have been found to have impaired wound healing following both anorectal surgery and laparotomy. This study aims to determine whether the healed wounds from HIV and AIDS patients have an impaired intrinsic strength compared to non-HIV patients.
Method: The healed scars of patients with HIV and AIDS who were undergoing a subsequent surgical procedure were excised. The scars were examined immediately by tensionometry and the load extension curve used to calculate values of ultimate strength, resilience (energy absorbed to elastic limit), toughness (total energy absorbed before rupture) and extension to breaking point. A non-HIV group with scars in the same range of maturity as the HIV group also undergoing revision surgery were used as controls and the results compared using the Mann–Whitney U-test.
Results: The wounds of 11 patients with HIV and AIDS were compared to 11 controls. Wounds in both groups were between 4 months and 4 years in maturity with no significant difference of maturity between the two groups ($P=0·158$). The median age of the HIV group was 39 (range 29–60) years and that of the control group was 66 (range 28–83) years. There was no significant difference between the groups preoperative haemoglobin or albumin, however the white cell count was lower in the HIV group ($P=0·005$). When examined biomechanically, wounds from the HIV and AIDS group had a lower resilience ($P=0·0138$), toughness ($P=0·0138$) and maximum extension ($P=0·0235$) compared to those of the control group.
Conclusion: The wounds of patients with HIV and AIDS when measured biomechanically are weaker than those of non-HIV controls. This weakness of wound repair reflects an impairment of the healing process in these patients, and supports the clinical data which show poor wound healing following laparotomy and anorectal surgery.

Poster 019

Acute appendicitis and menstruation

N. Evgenikos, J. McLaren and D.A.D. Macleod *Department of Surgery, St John's Hospital at Howden, Livingston, West Lothian*

Background: This study aimed to determine the association of menstruation with acute appendicitis.
Method: Prospectively collected data utilizing computer-assisted diagnosis of acute abdominal pain used to review patients with histologically proven acute appendicitis.
Results: One thousand and forty-one consecutive patients with histologically confirmed acute appendicitis were studied between 1981 and 1990. Only 366 patients were female, of whom 314 were having menstrual cycles. Twenty-four patients were excluded (eight patients were pregnant, seven patients had missed a period without confirmed pregnancy and nine patients had no record in the notes of their menstrual cycle). The median age of the 290 patients studied was 21·2 years, range 9·7–50·5 years. Patients were subdivided into two groups according to their use of the oral contraceptive pill. In the group of 208 patients who were not taking the contraceptive pill, 82 had acute appendicitis while they were in the proliferative phase of their cycle, 109 in the luteal phase and 17 (8·1 per cent) while menstruating, which was significantly less ($P<0{\cdot}05$) than expected, based on a standard 28 day cycle. Eighty-two patients were on the contraceptive pill, five of whom had acute appendicitis while they were having a 'period' ($P=0{\cdot}074$). Clinical presentation (symptoms, clinical signs, white cell count) were not statistically different in menstruating patients compared with those in the proliferative or the luteal phase of the cycle or on the oral contraceptive pill. There was no increase of gangrenous or perforated appendicitis in the menstruating group.
Conclusion: Appendicitis is less frequent in women during physiological menstruation.

Poster 020

The role of intra-aortic balloon counterpulsation in emergency general surgery: case presentation and review of literature

A.L. Khan, M.E. Flett, R.R. Jeffrey, A.K. Ah-See, K.G.M. Park and R.A. Keenan *Departments of General Surgery and Cardiothoracic Surgery, Aberdeen Royal Infirmary, Foresterhill, Aberdeen*

Background: Three cases are presented where intra-aortic balloon pump (IABP) was used prior to emergency non-cardiac surgery to stabilize the patient's cardiovascular status. The literature is reviewed for indications and clinical implications of counterpulsation and, in particular, the current concept of its use in emergency non-cardiac surgical procedures.
Method: Three patients who had recent myocardial infarction and required emergency life-saving procedure were included in this study. The IABP was inserted into the femoral artery by a Seldinger technique and placed in aorta. It was synchronized with the patient's pulse in a 1:1 ratio. The patients were monitored in the intensive care unit in the postoperative period.
Results: IABP successfully maintained the patients' cardiovascular status in the perioperative period.
Conclusion: IABP is a safe mechanical circulatory assistance device that improves cardiac function and reduces the risk of perioperative cardiac morbidity and mortality, although the experience is limited.

Poster 021

The driving force in trochar insertion

P.A. Super, C. Kelty and C.J. Stoddard *Royal Hallamshire Hospital, Sheffield*

Background: Insertion of the first trochar during the 'closed method' of creating pneumoperitoneum remains one of the most hazardous manoeuvres in laparoscopic surgery, with complications such as major vascular and bowel injuries. The ease with which trochars are inserted through the abdominal wall may well have some bearing on these complications.
Method: A range of both disposable and reusable trochars was investigated in experiments utilizing a hand-held pressure transducer and an abdominal wall model reconstructed with animal hide. Multiple insertions were performed and mean force of insertion recorded. A comparison of trochars was made and results listed in the following table.
Results:

Trochar type	Mean pressure (lb/in^2)
Best disposable	2·76 (0·12)
Best reusable	3·42 (0·03)
ANOVA	$P>0{\cdot}05$
New reusable	3·42 (0·03)
Used reusable	4·80 (0·05)
ANOVA	$P<0{\cdot}001$

Values in parentheses are SEM.

Conclusion: The effect of previous use on trochar performance demonstrates an obvious disadvantage of reusable instruments. The excessive force required to insert some trochars may place the patient more at risk of trochar injury.

Poster 022

Robotic assistant for laparoscopic cholecystectomy (Endosista): a clinical trial

S. Aiono and J.M. Gilbert *Department of Surgery, Wexham Park Hospital, Slough*

Background: Laparoscopic cholecystectomy usually requires an assistant to hold the telescope and camera, but camera control by the assistant is of varying quality, often unsatisfactory or unavailable. The aim of this study was to assess a robotic camera-holding device (Endosista) controlled by the surgeon's head movements in a clinical trial, and to compare it with a human camera holder.
Method: Patients undergoing laparoscopic cholecystectomy were randomized to have either the robotic or human assistant, with conversions to open operation excluded. Operating time, technical problems, the surgeon's and scrub nurse's subjective assessment, and complications were recorded. Consultants and trainees participated in the trial.
Results: Forty-two patients were randomized to Endosista (22) or manual assisted operations (20). Mean operating time with Endosista was 74 min (SEM 4 min) and 71 min with manual (SEM 5 min). There was no significant difference in operating times on an analysis of variance at the 95 per cent level. Use of the Endosista was readily learned, with no significant effect of occasion on operating time. Direct head control of the Endosista and the steady image provided were of significant benefit. The device was safe in use.
Conclusion: Endosista is a significant development for laparoscopic cholecystectomy, and is a safe alternative to a human assistant, providing a steady and high-quality image. Its use is easily learned by consultants and trainees.

Poster 023

The implications of a large population of intravenous drug abusers on surgical practice

M. Keshtgar, A. Shankar, L. Barnes, T. Davidson and I. Taylor
The Department of Surgery, University College Medical School, London

Background: The aim of this retrospective study was to assess the surgical complications associated with intravenous drug abuse and the resource allocation specifically associated with their treatment.

Method: All emergency surgical admissions to UCL Hospitals with complications of intravenous drug abuse over a 19-month period were audited (April 1996 to September 1997). Periods of in-patient care, surgical interventions, vascular complications, drug and total cost were calculated.
Results: Ninety-four intravenous drug abusers (31 women, 63 men of age range 18–49 years) were admitted. The majority of admissions were for localized sepsis associated with injection sites ($n = 90$) and four patients developed major vascular complications. Eighty-five per cent of patients required surgical intervention ($n = 80$). Of the total, 9 per cent ($n = 8$) were known to be either HIV or hepatitis B/C positive. The mean length of stay was 4·9 days (SD 5·93). The total cost of treatment was £130,000 and the mean cost per patient was £1382.
Conclusion: Although most patients had localized sepsis, a minority developed vascular complications necessitating more complex intervention with its associated financial implications. There is significant workload and resource implication for surgical units providing care to inner city drug abusers

Poster 024

Chronic abdominal pain and adhesions: patient assessment and surgical management with adhesiolysis and insertion of a bioresorbable membrane

S.G. Appleton, K.M. Haire*, S.P.G. Padley† and J.N. Thompson
*Departments of Surgery, *Anaesthetics and †Radiology, Chelsea and Westminster Hospital, London*

Background: The aim of this study was to assess our experience with patients whose intra-abdominal adhesions were thought to be causing symptoms and, in particular, the possible role of a new bioresorbable adhesion-prevention barrier (Seprafilm™).
Method: A review of patients referred with chronic abdominal pain attributed to intra-abdominal adhesions.
Results: Forty-one patients were referred between January and October 1997 for consideration of treatment for abdominal adhesions. There were 37 women and four men, and the median age was 45 (range 23–77 years). The median duration of symptoms was 6 (range 1–26 years). Two patients presented with purely obstructive symptoms, the remainder had chronic, disabling abdominal pain. All patients had undergone previous operations (laparoscopies: median 1, range 0–6; laparotomies: median 2, range 0–7). All patients had been extensively investigated elsewhere prior to referral. Fifteen of the 41 patients underwent an initial visceral slide ultrasound scan to look for the presence of adhesions to the undersurface of the abdominal wound. Of these 15 scans, six suggested adhesions to the back of the abdominal wound and in five no adhesions were present. In four the result was uncertain. The uncertain results were in wounds in the suprapubic region where the effects of exaggerated respiration are minimal. Six patients had a barium meal and follow-through, this showed no evidence of adhesions or obstruction in five but in one patient there was a suggestion of small bowel tethering which was confirmed at operation. Three patients underwent a barium enema examination which in one patient showed mild diverticular disease. Fifteen of the 41 patients went on to have a laparotomy with division of all adhesions and insertion of a bioresorbable membrane in an attempt to reduce adhesion reformation. Eleven of these patients have been seen postoperatively at 6 weeks or later. Ten of these patients report an improvement in their symptoms. Nine patients had a visceral slide ultrasound scan at a mean of 6 weeks postoperatively. Eight out of the nine scans were negative for adhesions. The one patient with a positive adhesion scan postlaparotomy was also the only patient to report a worsening of his symptoms.
Conclusion: Chronic abdominal pain attributed to adhesions is often complex and requires careful assessment and investigation before consideration of further adhesiolysis. A bioresorbable membrane has the potential to reduce adhesion reformation and offer symptomatic improvement, at least in the short term.

Poster 025

Central venous catheter-related sepsis: the inside story

B.M. Dobbins, P. Kite*, M.H. Wilcox*, S.P.L. Dexter, J. Bong, I.G. Martin and M.J. McMahon *Academic Department of Surgery and *Microbiology, The General Infirmary at Leeds, Leeds*

Background: Central venous catheter (CVC) tip roll has traditionally been used as the gold standard for diagnosing catheter-related sepsis (CRS) and has been the basis for the designs of new antimicrobial CVCs. This study was designed to look at the endoluminal and extraluminal segments of CVCs and to assess their significance in the development of CRS.
Method: Two hundred and thirty patients with suspected CRS were assessed over a 2-year period. The extraluminal colonization of CVCs was assessed using the tip roll technique, and endoluminal colonization using brush and tip flush techniques. CVC hub, skin and peripheral blood cultures were also performed. Scanning electron microscopy (SEM) was performed on proven cases of CRS (CRS defined as a positive catheter culture and associated peripheral bacteraemia with the same organism) to assess bacterial biofilms on both extra and endoluminal surfaces.
Results: Fifty-five cases of CRS were diagnosed (coagulase negative staphylococcus 20, *staphylococcus aureus* 14, candida 11, enterococcus 7, Gram-negative bacilli 3). Extraluminal, endoluminal and hub cultures were positive in 91 per cent, 100 per cent and 75 per cent of cases, respectively. More than 1000 colony-forming units were isolated from 45 per cent of extraluminal and 91 per cent of endoluminal samples. SEM performed on 12 cases of CRS showed significant endoluminally colonized biofilm, from hub to tip. SEM was unable to demonstrate extraluminal bacterial colonization in any of the CVCs assessed.
Conclusion: Endoluminal CVC colonization is highly significant in the pathogenesis of CRS, can be sampled *in situ* and should therefore replace extraluminal sampling in the diagnosis of CRS. Failure to coat the endoluminal surfaces of antimicrobial CVCs may explain why the use of these expensive catheters has failed to reduce CRS rates significantly.

Poster 026

What time of day should a urinary catheter be removed?

N.R. Hall, C. Clune, R.C. Macdonald and P.J. Holdsworth
Department of Surgery, Huddersfield Royal Infirmary, Huddersfield

Background: Urinary catheters are common on surgical wards yet there is little evidence upon which to base policy regarding the timing of their removal. This study was designed to determine whether urinary catheters should be removed in the morning or evening.
Method: All patients under the care of two consultants on a single general surgical ward with a short-term indwelling urinary catheter were prospectively randomized to removal either between 0700 and 0900 hours (early group) or between 2100 and 2300 hours (late group). End points included time to first void, volume of first void, frequency within the first 24 h, disturbance of normal sleeping hours and urinary retention.
Results: Of 123 patients, 66 were randomized to early removal and 57 to late removal. These groups were similar with respect to age, type of surgery and type of catheter. There was no significant difference between the groups of time to first void (mean 271 versus 327 min) but those undergoing early removal had a smaller first void (mean 221 ml versus 313 ml, Mann–Whitney, $P = 0·012$). The majority of those in the late group had their first void before 0600, and therefore had a disturbed night's sleep. Frequency of micturition was similar in each group. Recatheterization for retention was required in three patients in the early group (at 1500, 2330 and 0620 hours) and one in the late group (at 1200 hours) ($P > 0·2$).
Conclusion: There appears to be no particular medical advantage to catheter removal in the morning or evening. Late removal is associated with disturbance of sleep for micturition and early morning removal is preferable

Poster 027

The 'guarding probe': a laboratory assessment of a new device to measure abdominal rigidity in surgical patients

M.S. Whiteley, A.R. Davies and M. Perkins *Princess Margaret Hospital, Swindon and Royal United Hospital, Bath*

Background: Abdominal rigidity, or 'guarding', is a fundamental but subjective surgical sign that influences many clinical decisions. The aim of this project was to develop a device capable of objectively measuring guarding.
Method: We developed a portable 'guarding probe' which simulates the action of the surgeon's hand when examining an abdomen. The device is pressed on to the patient's abdomen; displacement of a central probe is continuously correlated with the pressure generated at its tip. Data are automatically transferred to a laptop computer and plotted on a graph, the gradient of which gives a numerical value for guarding. We have assessed the guarding probe on a laboratory model and a small group of patients admitted with abdominal pain.
Results: a) In the laboratory model we used an inflatable model to simulate four different tensions in a mock 'abnormal wall' assessed by an experienced surgeon to be between 'normal' and 'rigid'.

Inflation pressure	Mean score	Range	Variance
5 mmHg	1·20	0·97–1·35	0·018
10 mmHg	1·61	1·53–1·74	0·005
15 mmHg	2·23	2·03–2·37	0·011
20 mmHg	2·81	2·74–2·99	0·007

b) In six patients the guarding probe was able to distinguish the three with peritonitis (score >1·20) from the three without peritonitis (score <1·00).
Conclusion: The guarding probe is a new device that can provide an objective score for abdominal rigidity or 'guarding', with excellent reproducibility in a laboratory model. Early clinical evidence suggests that this might be reproduced in the clinical setting.

Poster 028

Comparisons between NHS and private hospitals in the surgical management of inguinal hernia

D.C. O'Riordan, M. Morgan, A.N. Kingsnorth, N.A. Black, S. Ambrose, P. Jones, S. Raimes, R. Taylor, D. Watkins and H.B. Devlin *On behalf of the Steering Committee, The National Groin Hernia Outcomes Project, The Surgical Epidemiology and Audit Unit, The Royal College of Surgeons of England*

Background: This study aimed to compare current practice between the NHS and independent sectors in the surgical management of inguinal hernia in the UK.
Method: All surgeons and hospitals in two regions (South Thames and Northern and Yorkshire) performing groin hernia repair were identified and invited to participate. Participating surgeons completed a questionnaire for all patients over 18 years undergoing elective and emergency inguinal hernia repair between July and October 1996.
Results: Three hundred and eighty-five surgeons in 131 hospitals were identified. One hundred and eighteen hospitals participated. Two hundred and seventy-six of 368 (75 per cent) surgeons in these hospitals agreed to participate. Questionnaires from 5038 of 5556 patients were returned (90·7 per cent). Inguinal hernia repair was required in 4759 (94·5 per cent). Of these, 705 (15·1 per cent) were performed privately. Significantly more private operations (20·6 versus 10·1 per cent) were performed in South Thames. Fewer private operations (26 versus 42·5 per cent) were performed as planned day cases ($P<0{\cdot}0001$ χ^2). There was no significant difference in the rates of use of antibiotics. Fewer private cases were performed on an urgent or emergency basis (0·6 versus 2·8 per cent $P<0{\cdot}005$ χ^2) and fewer (3·0 versus 8·4 per cent) were in ASA class 3, 4 or 5 ($P<0{\cdot}0001$ χ^2). More private cases were performed using local anaesthesia (8·2 versus 5·4 per cent $P<0{\cdot}001$ χ^2).
Conclusion: Patients having inguinal hernia repairs performed privately were more likely to have them repaired laparoscopically. This may be because the costs of disposable equipment are too high for routine NHS use. More private operations were also performed using an open onlay mesh repair. More cases were performed using local anaesthesia but the rate was still very low. Fewer private operations were performed as planned day cases despite the pressures of private insurers. Private patients had a lower ASA score and were less likely to be performed on an urgent or emergency basis, suggesting differing case mixes. Significantly more private operations were performed in South Thames reflecting demographic differences.

Poster 029

Audit of 1125 surgical deaths from colorectal cancer in Scotland 1994–1996

D. Ziyaie[1], F. Marjoribanks[2], S.J. Nixon[2] and A.M. Thompson[1,2]
[1]*Department of Surgery, Ninewells Hospital, Dundee* [2]*Scottish Audit of Surgical Mortality, Royal College of Surgeons, Edinburgh*

Background and Method: The Scottish Audit of Surgical Mortality (SASM), which examines all deaths on surgical wards in Scotland, collected data on the 1125 patients with colorectal cancer (799 colonic, 326 rectal) who died on surgical wards in 1994–1996.
Results: Sixty-five per cent of patients were >70 years, mean age 74 years (range 20–96), 64 per cent were admitted as an emergency; 54 per cent of operations were urgent/scheduled urgent, 61 per cent performed by consultants. The cause of death was cancer in 45 per cent and cardiopulmonary disease in 28 per cent; 363 patients received terminal care alone. A post-mortem was performed in only 16 per cent of patients but added information in just 2·5 per cent. Surgical assessors identified adverse factors in the choice of operation (3·1 per cent), preoperative management (7·2 per cent), intraoperative management (5·6 per cent), where technical operative problems were encountered in 17 per cent of patients, and postoperative management (11·8 per cent). Anaesthetic assessors identified adverse factors in the use of ITU/HDU (23·3 per cent) and in postoperative management (12·2 per cent). Over the 3-year period 1994–1996, adverse surgical factors declined as a contributor to death (from 20·3 per cent to 15 per cent) or cause of death (from 3·8 per cent to 0·8 per cent); anaesthetic factors remained static as a contributor or cause of death at 11·6 per cent and 0·6 per cent, respectively.
Conclusion: The SASM Audit has been associated with a fall in adverse surgical factors contributing to or causing death in patients with colorectal cancer. There remains room for increased consultant presence in theatre and improvement in postoperative management.

Poster 030

An audit of clinicopathological staging of cancers in the upper gastrointestinal tract in the South and West health regions

D.H. Bennett for the Upper GI Expert Tumour Panel of the South and West Regional Cancer Organisation *South and West Regional Cancer Organisation, c/o Professor A.N. Kingsnorth, Department of Surgery, Derriford Hospital, Plymouth*

Background: The advent of Cancer Centres nationwide has resulted in the need to audit the standard of treatment each centre is offering, leading to the development of a Regional Cancer Organisation (RCO). The role of the RCO is to both develop the minimum standards of care acceptable and to monitor, through audit, the performance of care against these standards.
Method: Three tumours were chosen for evaluation, oesophageal, gastric and pancreatic. A questionnaire was sent to each of the 27 hospitals covered by the RCO, requesting a pathology report and surgeon's operation note for one case of the above three tumours (a total of 81 tumours). The pathology report and surgeon's operative note were assessed by four independent clinicians using a standard proforma (13 and 12 questions,

respectively) for each tumour and, where there was disagreement, the result was adjudicated by a single member of the Expert Tumour Panel.
Results: There was no response from two hospitals despite repeated requests and, in some cases, the hospitals were not performing surgery for all three malignancies. This left 65 tumours (80 per cent) for analysis. Only 47 operation notes (58 per cent) were received and, of these, one was benign, two were frozen sections and one was the wrong operation note for the pathology report received. Therefore only 43 tumours (53 per cent) could be analysed, 10 pancreatic, 17 oesophageal and 16 gastric. Of these 43 tumours, none of the pancreatic and oesophageal tumours and only one of the gastric tumours could be accurately staged from the information received. The commonest reason for failure to stage the tumours (49 per cent of cases) was insufficient information on the radial resection margins. The presence of locoregional spread was also poorly documented (58 per cent cases only) and the extent of the resection (72 per cent cases only).
Conclusion: This study clearly indicates the urgent requirement for the standardization of both operations notes and pathology reports in order to provide sufficient information for oncologists to assess the need for additional treatment and for audit between centres.

Poster 031

Transthoracic endoscopic sympathectomy — no sweat!

M. Simms, B. Braithwaite and B.R. Hopkinson *Queen's Medical Centre, Nottingham*

Background: There has been an increase in the use of transthoracic endoscopic sympathectomy (TECS) for the treatment of various conditions. The aim of this study was to review the results of a single centre.
Method: Between 1990 and 1996, 78 patients had 133 TECS procedures done; 70 patients were available for follow-up. Some 32 patients (23 female, mean age 26 years) were treated for hyperhidrosis of the axillae or hands.
Results: Seven (22 per cent) patients had residual pneumothorax; only one required chest drainage (3 per cent). One patient contracted Horner's syndrome (3 per cent) and six patients (19 per cent) had severe chest pain that delayed hospital discharge. At follow up (mean 3 years, range 6 months to 6 years), 93 per cent of patients who presented with palmar hyperhidrosis continued to have dry hands. Some 82 per cent of patients with axillary symptoms remained improved. Compensatory sweating occurred in 64 per cent of patients, gustatory sweating in 14 per cent and 36 per cent had continued neuralgia at the site-of-port insertion. Some 24 patients (18 female) of mean age 50 years had 38 limbs (14 bilateral, 10 unilateral) were treated for severe Raynaud's phenomenon of the hand. Early complications were similar to the hyperhidrosis group. TECS improved symptoms in all but three limbs (91 per cent). At follow-up (mean 29 months), 35 per cent of limbs continued to be better. Some 61 per cent of limbs had reverted to the preoperative state in a mean time of 17 months. TECS was done on 14 patients for angina, critical limb ischaemia or as an adjunct to upper-limb surgery.
Conclusion: These results show that TECS can produce excellent results for patients with hyperhidrosis of the hand and axilla. For those with Raynauds phenomenon the outcome is less good but sufficient to treat severe symptoms. Complication rates are low but the incidence of compensatory sweating is important. Most patients found the latter an acceptable price for dry hands.

Poster 032

Chronic groin pain following 'tension-free' hernioplasty

C.R. Paterson, D.M. Wright and P.J. O'Dwyer *University Department of Surgery, Western Infirmary, Glasgow*

Background: Chronic groin pain following inguinal hernia repair is a serious complication which may have a major effect on the patient's quality of life. The aim of this study was to examine the incidence of chronic groin pain following 'tension-free' hernioplasty.
Method: Between 1994 and 1996, 357 patients had mesh repair of a groin hernia under the care of one consultant. All have been examined for evidence of recurrence or chronic pain annually for 1–3 years.
Results: Results for chronic pain are as follows:

		Follow-up		
Year	No. patients	1 year	2 years	3 years
1994	113	16 (14%)	6 (5%)	7 (6%)
1995*	117	7 (6%)	4 (3%)	—
1996*	127	6 (4%)	—	—
Total	357	29 (8%)	10 (2·8%)	7 (1·9%)

*$P<0·05$ compared with 1994 group.

Twenty-four of the 29 (83 per cent) with chronic pain at 1 year complained of pain at the site of their hernia before operation compared with 62 per cent of the total number undergoing hernia repair. Chronic groin pain was more common after open than after laparoscopic repair 10 per cent versus 4 per cent ($P=0·02$). In six patients (1·7 per cent) the pain was of such severity that they required referral to the pain clinic.
Conclusion: The reduced incidence of chronic pain between operations performed in 1994 and 1995/96 suggests that this complication may be learning-curve related. As only two (0·6 per cent) have had evidence of recurrence, these data suggest that chronic pain after 'tension-free' hernioplasty is the most common long-term complication of this operation.

Poster 033

Value of preoperative and postoperative supplemental enteral nutrition in patients undergoing major gastrointestinal surgery

M.D. Palmer, S. Townsend, J.D. Harrison, C.J. Mitchell and J. MacFie *Combined Gastroenterology Unit, Scarborough Hospital, Scarborough, North Yorkshire*

Background: It has been proposed that supplemental enteral nutrition (SEN) administered to surgical patients in the postoperative period confers significant clinical benefit. We have investigated the potential advantages of SEN in 60 consecutive patients undergoing major excisional surgery.
Method: Patients were randomized to receive either normal diet or diet supplemented by commercially available nutrition 'sip feeds' (20 g protein, 600 kcal, 400 ml/day), for a minimum of 14 days prior to surgery and/or during the postoperative period. Pre- and postoperative weights, POSSUM scores, duration of hospital stay and any complications were recorded. Anthropometric measurements, serum proteins and liver function tests were serially measured. Patients were matched for age, sex and type of operation.
Results:

		Mean patient weights in kg (SEM)			
Group	Dietary supplement	Presentation	Pre-operative	Outpatient review	Duration of stay in days (SEM)
A ($n=15$)	Pre- + postoperative	62·1 (2·0)	61·8 (2·0)	61·2 (1·9)	11·8 (1·0)
B ($n=13$)	Pre-operative	64·0 (3·5)	61·1 (4·7)	54·0 (5·3)	12·8 (2·2)
C ($n=17$)	Postoperative	64·8 (3·1)	65·0 (3·1)	58·5 (3·4)	12·7 (1·4)
D ($n=15$)	None	69·8 (3·8)	71·5 (2·4)	68·5 (3·3)	13·4 (1·0)

All patient groups demonstrated a mean weight loss from time of randomization preoperatively to initial outpatient review following surgery (Table). Duration of hospital stay was the same in all groups. There were no inter-group differences in the incidence of complications, POSSUM scores, grip strength or biochemical indices.
Conclusion: Our results do not confirm the findings of others that short-term SEN confers significant clinical benefit.

Poster 034

The informed consent process in urgent abdominal surgery

R. Kay and A.K. Siriwardena *University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh*

Background: We have previously reported to the Association that contrary to general medical opinion, patients with acute abdominal pain perceive that they retain the ability to give informed consent. However, as replies to questionnaires are critically influenced by the nature of the questions asked, this study aimed to evaluate the true significance of our previous findings by using a modified, non-leading questionnaire and by the use of two control groups.
Method: A prospective study of all patients over the age of 16 years admitted to an acute surgical unit and undergoing urgent abdominal surgery during an 8-week study period. Factors interfering with patients' ability to give informed consent were identified. Patients were asked if they had received an explanation of common side-effects and complications and if they knew the grade of the doctor obtaining consent. A control questionnaire was put to the consent obtainer to ascertain if there had been a discussion of potential side-effects and if an attempt had been made to avoid obtaining consent from patients under the effects of analgesia. A further control questionnaire was put to patients undergoing elective abdominal surgery to test the hypothesis that these patients are better informed. All questionnaires incorporated a mini-mental state test to allow recognition of those patients cognitively impaired at the time of interview. A consecutive series of 86 patients undergoing urgent surgery was evaluated of which 18 were excluded leaving a study population of 68. Seventy-seven patients undergoing elective surgery formed the control group.
Results: Forty-eight (71 per cent) patients undergoing urgent surgery reported that pain did not interfere with their ability to ask questions. Forty-six (68 per cent) patients had received analgesia prior to giving consent of which 14 (30 per cent) reported that this interfered with the ability to ask questions. Significantly fewer patients undergoing urgent surgery felt they had received an explanation of potential side-effects/complications of surgery compared to elective patients ($\chi^2=7{\cdot}3$, $P<0{\cdot}01$). Fourteen (21 per cent) patients undergoing urgent surgery correctly identified the grade of the doctor obtaining consent compared to 30 (39 per cent) undergoing elective surgery. Fifty-eight (85 per cent) patients undergoing urgent surgery felt that they retained the ability to give informed consent. Thirty-nine (57 per cent) doctors checked whether the patient had received analgesia prior to obtaining consent. Potential side-effects were discussed by 31 (46 per cent) and 10 (15 per cent) discussed alternative therapeutic options.
Conclusion: This study confirms that patients perceive that they retain the ability to give informed consent despite the effects of abdominal pain and analgesia. There is relatively little discussion of potential side-effects and complications in patients undergoing urgent surgery.

Poster 035

Peritoneal inflammatory cytokine response is increased following laparoscopy with cold carbon dioxide

M.I. Puttick, C.C. Nduka, L. Yong and A. Darzi *Academic Surgical Unit, Imperial College School of Medicine at St Mary's Hospital, London*

Background: Recent work has shown that intraoperative hypothermia is a significant source of surgical trauma with wide-ranging physiological and immunological sequelae. The aim of this study was to examine the effect of intraperitoneal hypothermia during laparoscopy on local inflammatory cytokine response in an animal model.
Method: Inbred Wistar rats ($n=28$) were randomized to undergo insufflation with CO_2 at room temperature (~21°C) or normothermic pneumoperitoneum. The latter consisted of CO_2 insufflated at 37°C with additional radiant and forced-air warming postoperatively to maintain normothermia. At 4 h and 24 h rats were sacrificed and peritoneal lavage performed to assess production of tumour necrosis factor (TNF-α). In addition, peritoneal macrophages were isolated and their activation was assessed *in vitro*, as shown by their TNF-α release following endotoxin challenge. Peritoneal fluid and macrophage supernatants were analysed by ELISA and data analysed by *t*-test.
Results:

	Cold CO_2	Warm CO_2	Significance
Lavage TNF-α (pg/ml) 4 h	17·01 ± 2·13	13·86 ± 1·08	$P=0{\cdot}09$
Lavage TNF-α (pg/ml) 24 h	18·05 ± 2·76	11·79 ± 2·69	$P<0{\cdot}02$
PMØ 4 h TNF-α (pg/ml)	362·1 ± 64·75	512·0 ± 83·22	$P<0{\cdot}02$

Laparoscopy with cold CO_2 results in a significant reduction in local and core temperatures ($P<0{\cdot}05$) and a significant inflammatory cytokine response with increased priming of peritoneal macrophages.
Conclusion: In agreement with previous work, this study shows that perioperative hypothermic stress in the form of cold gas insufflation is a significant source of surgical trauma which may be amenable to correction.

Poster 036

An objective assessment of surgeons' psychomotor skills: validation of the MIST-VR laparoscopic simulator

N.J. Taffinder, R.C.G. Russell, I.C. McManus, J. Jansen and A. Darzi *Minimal Access Surgical Unit, Imperial College School of Medicine at St Mary's Hospital, London*

Background: This study aimed to develop objective criteria for assessing psychomotor skill on a virtual reality simulator and to validate these measurements by comparing surgeons of differing experience.
Method: Thirty subjects [experienced laparoscopic surgeons > 100 cases ($n=10$), trainee surgeons ($n=10$) and non-surgeons ($n=10$)] were given identical training on a virtual reality simulator (MIST-VR) to familiarize them with the equipment. The subjects were then asked to perform ten repetitions of a complex virtual task which involved two-handed co-ordination and use of a foot pedal to simulate diathermy. The position in space of left and right virtual instrument tips was tracked and the x,y,z co-ordinates recorded every 0·05 s. Comparison of these data with the x,y,z positions of the virtual tasks enabled the computer to calculate efficiency of movement (actual/ideal path length), number of past-pointing errors, number of sub-movements needed to complete the task and total time taken.
Results:

	Efficiency (path length ratio)	Errors (past pointing)	Sub-movements	Time taken
Experienced	2·3 (0·3)	4·7 (1·1)	10·1 (3·4)	13·3 (3·2)
Trainees	3·3 (1·3)	6·3 (2·3)	15·9 (4·4)	19·3 (5·4)
Non-surgeons	3·6 (1·0)	7·3 (2·2)	18·5 (6·1)	21·9 (6·7)
Significance (Kruskal–Wallis)	$P<0{\cdot}01$	$P<0{\cdot}02$	$P<0{\cdot}01$	$P<0{\cdot}01$

Values are mean (SD).

Conclusion: A virtual reality simulator can distinguish between experienced surgeons, trainee surgeons and non-surgeons by unbiased objective measurement. The ability to quantify technical expertise could have implications for training, examination and accreditation.

Poster 037

Aterial natriuretic peptide expression and secretion in laparoscopic and open surgery

D.J. Exon, M.J.J. Vesely, C.J. Green and S.J.D. Chadwick
Department of Surgical Research, Northwick Park Institute for Medical Research, Northwick Park and St Mark's Hospital, Harrow, Middlesex

Background: Abdominal insufflation required for laparoscopic surgery causes a significant reduction in femoral vein and inferior vena caval

(IVC) blood flow. We have recently shown that IVC pressure increases significantly on induction of pneumoperitoneum and is maintained until desufflation. Such venous pressure changes are not apparent during 'open' surgery. We considered the effect that these changes in venous pressure and flow have on the expression and secretion of atrial natriuretic peptide (ANP), an important regulator of cardiovascular function.
Method: Male Sprague–Dawley rats (weight 400–550 g) were randomized to control (anaesthetic alone), CO_2 pneumoperitoneum for 1 h (intra-abdominal pressure 8–10 mmHg) or laparotomy for 1 h. After the animals were killed, blood was taken by direct cardiac puncture for measurement of serum ANP (using an enzyme-linked immunosorbant assay) and atrial tissue removed for RNA extraction. Differential reverse transcription-polymerase chain reaction (with β-actin as the internal standard), was used to detect and semi-quantify the ANP mRNA present in 1 μg extracted RNA.
Results: The ANP mRNA data are shown below as a percentage of the control.

	ANP mRNA levels	[ANP] pg/ml
Control		93·5 (12·8)
Pneumoperitoneum	66·8 (7·5*)	57·4 (9·3)
Laparotomy	29·7 (1·0†)	37·9 (9·9‡)

Values are mean (SEM). For each experimental group n = 7 to 9. *P = 0·05 and †P = 0·001 versus control (t-test); ‡P = 0·05 versus control (Mann–Whitney U-test).

Conclusion: There is a significant reduction in the expression of ANP mRNA after 1 h pneumoperitoneum, with a similar trend in ANP release. While this fall corresponds to the observed fluctuation in IVC pressure and blood flow, such a mechanism does not explain the more pronounced reduction in ANP seen following laparotomy. We suggest an alternative mechanism controls ANP expression and release in open surgery, which is independent of venous pressure.

Poster 038

The use of carbon dioxide laser to control cutaneous limb recurrence from malignant melanoma

A.J. McKay, M.K. Lingam and D. Byrne *Department of Surgery, Gartnavel General Hospital, Glasgow*

Background: Surgical excision of cutaneous malignant melanoma metastases is only practical when the number of lesions is small. In lesions confined to the limbs, isolated limb perfusion (ILP) has been our treatment of choice for the past 10 years. This, however, is not possible in all patients. We present our experience with carbon dioxide laser ablation as an alternative treatment in the control of cutaneous metastases in such patients.
Method: Between September 1992 and November 1996, 29 patients (20 female and nine male) underwent a total of 57 laser treatments. The lesions were situated on the face, chest, arm and leg. The number of lesions per patient ranged from two to 43 nodules. A Sharplan 1030 portable carbon dioxide laser was used. All procedures were carried out under general anaesthesia. Each lesion was destroyed using a focused laser beam of 10–20 watts with a beam size of 0·5–1·0 mm.
Results: Twelve patients have had multiple laser treatment in the attempt to control local disease, the most being seven treatments in one patient. At a mean follow-up of 18 months, six patients have died from the disease. In the 23 patients who are alive, 18 have had no recurrence of the disease and five have had partial control of local disease.
Conclusion: Our experience suggests that carbon dioxide laser ablation of cutaneous metastases is a minimally invasive procedure which gives effective palliation.

Poster 039

The confidential enquiry into surgical training

The Advisory Committee on Audit (D.R. Harper) *Royal College of Surgeons of Edinburgh, Edinburgh*

Background: This study aimed to audit the contribution made to junior surgical training in the operating theatre by training consultants.
Method: Two hundred Scottish surgeons across all specialities collaborated in this study by agreeing that data from theatre computer systems could be directly accessed by the Royal College of Surgeons of Edinburgh. In the event these systems could only produce reliable data with respect to the work of a third of participating consultants. The data were standardized by examining certain representative operations only, the indicator operations, which varied from speciality to speciality. Each surgeon's data were returned to him compared with the pooled data of all the surgeons in the speciality.
Results: The data allowed analysis of five scenarios for 968 operations: trainee operating with the consultant surgeon assisting, consultant surgeon operating with the trainee assisting, a trainee operating with a trainee assisting, a trainee operating alone, and other scenarios.

There was considerable variation between and within specialities. For example, the average percentage of cholecystectomy cases where a trainee was taken through by a consultant was 21·5 per cent. However, the caseload of the surgeon bore no relationship to the proportion of times that his trainee had the opportunity of hands on experience, although by comparison with the previous year many surgeons improved their practice.
Conclusion: Surgeons are open to the idea that their contribution to training at the operating table is sufficiently important to allow their data to be used in this way. There is evidence that this audit changes practice for the better. Hospitals having trainees should have systems to allow this kind of audit to take place.

Poster 040

Scottish audit of surgical mortality from pancreatic cancer 1994–1996

M.A. Jahan, F. Marjoribanks, S.J. Nixon and A.M. Thompson
Department of Surgery, University of Dundee and Scottish Audit of Surgical Mortality, The Royal College of Surgeons of Edinburgh

Background: The Scottish Audit of Surgical Mortality collects data on the management of patients who die in surgical wards. The aim of this study was to identify areas for improvement in the management of patients who die from pancreatic cancer.
Results: During the first 3 years of the audit (1994–1996), there were 334 deaths; 165 (75 per cent) were emergency admissions, 133 (40 per cent) had an operative procedure. In 147 (44 per cent) the patients' treatment was limited and 94 (28 per cent) had terminal care. Seventy (53 per cent) operations were performed as urgent or emergency, 18 (14 per cent) had an open and shut laparotomy, but only eight (2·1 per cent) deaths followed pancreatic resection. In 21 (16 per cent) patients there were intraoperative technical problems and 25 (19 per cent) patients required reoperation for complications. Adverse factors in surgical management were identified in 16 (12 per cent) patients and in anaesthetic management in six (5 per cent) patients. Postoperative care could have been improved in 23 (17 per cent) patients and 17 (13 per cent) who would have benefited from HDU/ITU care were denied it.
Conclusion: This study has identified areas for improvement in the management of patients with pancreatic cancer managed on surgical wards.

Poster 041

Thromboprophylaxis and the incidence of deep vein thrombosis and pulmonary embolism following laparoscopic surgery

C. Wong and B.I. Rees *University Hospital of Wales, Cardiff*

Background: Despite the increased risk of venothrombosis with laparoscopic surgery there is still great variation between surgeon's choice of thromboprophylaxis. We have reviewed the different thromboprophylaxis protocols and audited the venothrombotic rate following laparoscopic surgery at our hospital.

Method: A telephone survey of thromboprophylaxis regimen, used by surgical firms with an established laparoscopic practice in Wales, was conducted. In order to determine the effectiveness of these regimes an audit of venothrombotic complications at our hospital following laparoscopic procedures for the past 5 years was also conducted.
Results: There were 19 surgical firms in 14 centres. Four surgical firms (21·1 per cent) do not use routine prophylaxis. Of the remaining 15 (78·9 per cent) firms, 13 (86·7 per cent) use TEDS, 7 (53·9 per cent) use IPCS and 13 (86·7 per cent) use miniheparin routinely. Eleven firms (57·9 per cent) will alter their prophylactic regime with high-risk patients. None of the firms reported venothrombotic complications that they were aware of. Between 1991 and 1996 there were 2224 laparoscopic procedures performed at our hospital. Of these, 1202 procedures were performed by general surgeons with the majority being laparoscopic cholecystectomy. The rest were mainly gynaecological diagnostic procedures. There were no venothrombotic complications following laparoscopic procedures during this period.
Conclusion: There is great variability of choice of thromboprophylaxis between surgeons for laparoscopic surgery. Surprisingly, the clinical result does not appear to support the increased risk of venothrombosis following laparoscopic surgery.

Poster 042

Good outcome from surgery for ampullary tumour: a 16-year review

S.K.C. Toh, N. Davies, P. Dolan, C. Worthley, N.C.W. Townsend and J.A.R. Williams *Hepatobiliary and Pancreatic Surgical Unit, Royal Adelaide Hospital, Australia*

Background: Ampullary tumours are rare with a few reported series but appear to have a better prognosis than pancreatic neoplasms. The aim was to review the management and long-term outcome of patients admitted to the Surgical Unit with an ampullary tumour from January 1980 to April 1997.
Method: Patient records were reviewed.
Results: Twenty-six cases of ampullary tumours were admitted, 21 adenocarcinoma, five benign tumours including two neuroendocrine tumours (carcinoid, gangliocytic paraganglioma) and three adenomas. All patients had endoscopic biopsy. The benign tumours were found in five men, aged 42–73 years (mean 58 years) and were treated by transduodenal local resection (4) and Whipple procedure (1). One in-hospital death at 2 months occurred from anastomotic leak in the Whipple procedure patient. Ten men and 11 women had adenocarcinoma, with a mean age of 74 years (range 43–91 years). Patients presented with jaundice (17), pain (9), weight loss (8), lethargy (4), recurrent pancreatitis (2), anaemia (2), liver metastasis (1). Two patients were asymptomatic with tumours found incidentally at cholecystectomy. One patient aged 89 years had palliation only. Two patients had biliary stenting only (one aged 91 years, the other aged 67 years who refused surgery). Three patients had preoperative stenting. Six patients had a Whipple procedure, seven had a pylorus-preserving pancreaticoduodenectomy (PPPD), two had local resections, two had palliative bypass surgery. There were no 30-day or in-hospital mortalities. The 5-year survival following PPPD was 43 per cent and Whipple 33 per cent. Both local resection patients died within 5 years, but not from recurrent disease.
Conclusion: Our experience suggests that benign ampullary tumours may be safely resected locally and that pancreaticoduodenectomy for adenocarcinoma of the ampulla has a favourable operative and long-term mortality.

Poster 043

Audit of deaths from acute pancreatitis in the south east of Scotland 1995–96: evidence for variation in management?

A.C. de Beaux and S.J. Nixon *Department of Surgery, Western General Hospital, Edinburgh*

Background: This study aimed to undertake an audit of all deaths under surgical care from severe acute pancreatitis in the South East of Scotland, 1995–96.
Method: All patients with a diagnosis of acute pancreatitis reported to the Scottish Audit of Surgical Mortality (Edinburgh Office) during 1995–96 were included. Age, sex, surgical intervention, mode of death, length of stay, deep venous thrombosis prophylaxis and intensive care unit admission were noted.
Results: Sixty-one deaths were reported. The median age was 70 (range 31–91) years with 13 patients (21 per cent) under the age of 55 years. Thirty-six patients were male, seventeen patients underwent surgical intervention, necrosectomies (13), drainage of pseudocyst (2), ERCP (2). Diagnosis of severe acute pancreatitis was made at presentation in 56 patients (92 per cent), at post-mortem in four and at laparotomy in one. The predominant mode of death was multiple organ failure (49 patients). Of the remainder, three died from pancreatitis complicating terminal cancer, three from myocardial infarction, three from pulmonary embolus (one in the presence of multiple organ failure), two from peripancreatic haemorrhage, one from a bleeding duodenal ulcer and one from a stroke. The median time from admission to death was 8 days (4·5 days in those >55 years versus 16, <55). Twenty patients (33 per cent) died within the first 48 h. Thirty-five patients were managed in specialist units, 14 of whom had been transferred from other units. In three patients, delay in transfer was thought to contribute to their death. Ten out of 26 patients (surviving >48 h) were not transferred to specialist units despite their diagnosis being known and there being no decision to limit treatment. While pulmonary embolus contributed to death in three patients, deep vein thrombosis (DVT) prophylaxis was not used in 29 patients (48 per cent); seven of whom had deranged coagulation but no reason was given in 22 patients. Forty patients (66 per cent) were admitted to the intensive care unit (ICU). There were no ICU beds available for three patients and a decision to limit treatment was made for eight patients. No reason was given for the remaining 10 patients whose ages ranged from 75 to 89 years.
Conclusion: A third of patients dying from acute pancreatitis rapidly develop MOF and die within 48 h of admission. Some patients were either not transferred to specialist units or were transferred late; DVT prophylaxis was not universal; ICU facilities were withheld from a number of elderly patients, but the reasons for such variation in surgical management cannot be eludicated from this audit.

Poster 044

Prospective randomized trial of mini-cholecystectomy versus laparoscopic cholecystectomy: a single surgeon study

J.W. Faux, C. Terzi and F.P. McGinn *Southampton General Hospital, Southampton*

Background: This study aimed to prospectively examine laparoscopic and mini-cholecystectomy and discover if they are comparable operations for the treatment of patients requiring elective cholecystectomy.
Method: Patients awaiting elective cholecystectomy without clinical suggestion of bile-duct stones were randomized to either laparoscopic or mini-cholecystectomy. Procedures were all performed by one surgeon (FPMcG) with experience (60 cases) of both forms of surgery.
Results: Operative duration was shorter and postoperative stay longer for mini-cholecystectomy (53 versus 69 min, $P<0{\cdot}01$, 3·5 days versus 3 days (mean) $P<0{\cdot}05$; Mann–Whitney U-test). Major complications were more common after laparoscopic cholecystectomy (5 versus 1, $P<0{\cdot}05$; Fishers exact test).
Conclusion: This study suggests that postoperative complications after laparoscopic cholecystectomy may be more common than after mini-cholecystectomy. A large, multi-surgeon, prospective study is required to establish the safety of laparoscopic cholecystectomy compared with mini-cholecystectomy.

Poster 045

Management of hepatobiliary Ascaris infestation after failed medical treatment

I.J. Beckingham*, S.N. Cullis, J.E.J. Krige, P.C. Bornman and J. Terblanche **Department of Surgery, Nottingham, and Surgical Gastroenterology and Department of Surgery, University of Cape Town & Groote Schuur Hospital, South Africa*

Background: *Ascaris lumbricoides* is endemic in much of Africa. Around 20 per cent of all ascariasis-related admissions are for hepatobiliary

disease and the majority of these patients will respond to standard medical therapy (cessation of oral intake, i.v. fluids, antispasmodics, and anti-helminthic drugs). When medical therapy fails, surgery has been the traditional treatment of choice. The aim of this study was to determine the role of endoscopic retrograde cholangiopancreatography (ERCP) and surgery in the management of hepatobiliary Ascaris.
Method: Analysis of all patients undergoing ERCP or surgery for ascariasis of the biliary or pancreatic system unresponsive to standard medical therapy. Worms were extracted using snare or biopsy forceps. Success was defined as clearance of worms and eradication of symptoms.
Results: ERCP extraction was attempted in 25 patients with success in 19 (76 per cent). The median number of procedures was 1 (range 1–5). Concomitant calculi were present in six patients. Two patients suffered complications: 1 empyema, 1 pseudocyst. Failed clearance of worms by ERCP was due to gallbladder-related disease in two patients, strictures in three and intrahepatic worms in one patient. All six patients were successfully treated by surgery [laparoscopic cholecystectomy (1), open cholecystectomy (1), exploration of CBD (1), roux-en-Y hepaticojejunostomy (2) and longitudinal pancreaticojejunostomy (1)].
Conclusion: ERCP is successful in the treatment of Ascaris infestation resistant to medical therapy in 76 per cent of patients. Surgery remains important in the management of Ascaris infestation associated with the gallbladder, and with biliary or pancreatic strictures.

Poster 046

Magnetic resonance-guided interstitial laser thermoablation in an isolated perfused organ model

S.W.T. Gould, G. Lamb, N. Vaughan, R. Goldin, W. Gedroyc and A. Darzi *Academic Surgical Unit, Imperial College School of Medicine at St Mary's Hospital, London*

Background: Magnetic resonance imaging (MRI) is the most sensitive radiological modality for on-line monitoring of interstitial laser thermoablation (ILT). We developed an isolated perfused organ model to evaluate the relationship between energy deposition and lesion size in the presence of the heat-sink effect from simulated blood flow.
Method: In fresh porcine livers an MR-compatible perfusion cannula was placed within the portal vein. The livers were positioned within a laparoscopic simulator in a 0·5T MR scanner and connected via 15 m of silastic tubing to a single-chamber cardiac perfusion pump with heat-exchanger (positioned outside the magnet room). Perfusate return was via sump drainage from the simulator. The livers were perfused at 500 ml/min with University of Wisconsin solution at 4°C. A freshly cleaved 600 μm diameter bare Nd:YAG laser fibre was placed within the parenchyma together with an MR compatible thermocouple. Real-time MR monitoring was performed with a novel colour subtraction sequence during lesion formation at 5 W for 20 min or 10 W for 10 min (total energy deposition 6000J). The temperature at the tip of the laser fibre was measured at minute intervals. The maximum dimensions of the resulting lesions were measured at histology and compared with those predicted from the on-line MR imaging.
Results: Porcine livers could be perfused using this model at 4°C for 8 h with maintenance of tissue viability as assessed by histological methods. The spatial and temporal extent of lesion formation was monitored successfully using the colour subtraction sequence in each case. There was a significant difference ($P<0{\cdot}01$) between maximum temperature (mean ± SD) reached at 5 W (34·3 ± 18°C, range 13–63°C) and at 10 W (84·2 ± 31·5°C, range 25–153°C). Maximum lesion size (mean ± SD) at 5 W was 1·3 ± 0·4 cm (range 0·8–1·6 cm) and 2·0 ± 0·3 cm (range 1·5–2·5 cm) at 10 W. The difference between mean lesion size at 5 W and 10 W was significant ($P<0{\cdot}01$). Lesion size measured at histological examination correlated closely with that predicted from the image ($r^2=0{\cdot}84$). The smaller lesions occurred when the fibre was placed in close proximity to a large intrahepatic branch of the portal vein.
Conclusion: This perfused organ system allows the effect of simulated blood-flow on MR-monitored ILT to be studied *in vitro* and could potentially be applied to the study of ILT in perfused human tissues at normal body temperature. The maximum temperature reached during formation of an ILT lesion, and hence maximum lesion size, depends on both the laser power settings and the proximity of the fibre to large blood vessels.

Poster 047

Increased nitric oxide activity in acute pancreatitis

R.A. Al-Mufti, R.C.N. Williamson and R.T. Mathie *Department of Gastrointestinal Surgery, Hammersmith Hospital, Imperial College School of Medicine, London*

Background: Over-production of nitric oxide (NO) via induction of the inducible NO synthase (iNOS) is increasingly recognized as an important factor in the haemodynamic disturbances of several inflammatory states. The aim of this study was to identify the role of NO in a caerulein-induced model of acute pancreatitis in the rat.
Method: Acute oedematous pancreatitis was induced by caerulein in 10 adult male Wistar rats. Blood pressure and plasma NO metabolites were measured at 0 and 7 h, pancreatic iNOS activity was assayed biochemically by measuring conversion of radio-labelled L-arginine to L-citrulline. In addition, the pancreatic expression and cellular localization of iNOS and nitrotyrosine (a marker of peroxynitrite-induced oxidative tissue damage) were characterized by immunohistochemistry. Data were compared to those in saline-treated controls ($n=10$).
Results: Compared with controls at 7 h, the pancreatitis group displayed raised plasma NO metabolites [mean (SEM) 70·2 (5·9) versus 22·7 (2·2) μmol/l, $P<0{\cdot}0001$] and reduced mean arterial blood pressure [88·7 (4·6) versus 112·8 (4·1) mmHg, $P=0{\cdot}001$]. There was marked iNOS activity in the pancreatitis group [3·1 (0·34) versus 0·1 (0·01) pmol.mg protein^{-1}.min^{-1}, $P<0{\cdot}0001$]. There was also increased localization of iNOS within vascular smooth muscle cells ($P=0{\cdot}003$ versus controls), with positive perivascular staining for nitrotyrosine ($P=0{\cdot}0012$ versus controls).
Conclusion: In this experimental mode of acute pancreatitis, iNOS induction and oxidative tissue damage in the pancreas is associated with raised systemic NO and arterial hypotension. Excess production of NO arising from the inducible NO synthase may be an important factor in the systemic and local haemodynamic disturbances associated with acute pancreatitis.

Poster 048

Comparison of laparoscopic cholecystectomy in obese, morbidly obese and non-obese patients

B.J. Ammori, D. Davides, A. Vezakis, I.G. Martin, M. Larvin and M.J. McMahon *Leeds Institute for Minimally Invasive Therapy, The General Infirmary, Leeds*

Background: This study aimed to evaluate the influence of morbid obesity on feasibility and outcome of laparoscopic cholecystectomy (LC).
Method: Data collected prospectively from 864 consecutive patients undergoing LC at our institution between 1990 and 1997 were analysed. This series represents a continuing policy of LC for all-comers. There were 659 non-obese (Group I: BMI <30 kg/m^2), 188 obese (Group II: BMI 30–40 kg/m^2) and 17 morbidly obese patients (Group III: BMI >40 kg/m^2). Groups were well matched for age and sex distribution.
Results: A trend towards increased conversion rate, operative time and postoperative complications, and reduced ability to obtain cholangiography was observed with increasing obesity. This, however, was not statistically significant (χ^2 test, $P>0{\cdot}05$). There were no operative deaths in either group. Postoperative hospital stay for LC was similar in all groups (median: 1 day).

	Group I	Group II	Group III
Conversions	15 (2·3%)	8 (4·3%)	1 (5·9%)
Mean operative time (min)	95	96	112
Postoperative complications	31 (4·7%)	11 (5·9%)	2 (11·8%)
Operative cholangiography*	491/570 (86%)	141/176 (80%)	10/14 (64%)
Bile duct exploration	28 (4·2%)	9 (4·8%)	1 (5·9%)

*103 (12 per cent) patients who had clear duct at preoperative ERCP, operated on by surgeons adopting selective cholangiography or underwent a planned laparoscopic duct exploration were excluded from this analysis.

Conclusion: LC in morbidly obese patients appears safe with no significant increase in operating time, postoperative complications, or hospitalization.

Poster 049

Bacterial colonization of the upper gastrointestinal tract is associated with septic morbidity in patients with acute pancreatitis

C.J. O'Boyle, B. Roy, P. Sudworth, C.J. Mitchell and J. MacFie
Combined Gastroenterology Unit, Scarborough Hospital, Scarborough, North Yorkshire

Background: Pathological colonization of the normally sterile upper gastrointestinal tract may be an important prelude to the development of septic complications in critically ill patients. We have correlated the results of nasogastric aspirate culture and severity of illness with the incidence of septic complications in patients presenting with acute pancreatitis.
Method: Thirty-four patients with acute pancreatitis underwent nasogastric intubation as part of standard clinical treatment. Gastric aspirate (10 ml) was obtained under sterile conditions and sent for microbiological culture. Physiological assessment scores (POSSUM) were measured in all patients. All septic events were recorded.
Results: Patients with multi-organism colonization had a significantly greater incidence of septic complications compared to those with single or no organisms isolated from the aspirate (6 of 8 versus 2 of 8 positive; 8 of 26 versus 18 of 26 negative, $P<0{\cdot}05$). Furthermore, patients with a low POSSUM score (<20) had a significantly lower incidence of septic events and aspirate culture growth. Lactobacilli were frequently isolated in non-septic patients (20 of 26, mean POSSUM score 17 ± 2) but were absent in all but one of the patients with septic complications (1 of 8; mean POSSUM score 34 ± 4, $P<0{\cdot}05$).
Conclusion: Bacterial colonization of the upper gastrointestinal tract predisposes to septic complications in patients with acute pancreatitis.

Poster 050

Oral eicosapentaenoic acid reduces experimental human pancreatic tumour growth in SCID mice

M.D. Barber, K.C.H. Fearon and J.A. Ross *University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh*

Background: We have previously shown that eicosapentaenoic acid (EPA) will inhibit the growth of human pancreatic cancer cell lines *in vitro*. This study aimed to assess the effect of dietary EPA upon the growth of a human pancreatic cancer cell line (MIAPaCa-2) as a xenograft in immunocompromised mice.
Method: Pieces of tumour were transplanted subcutaneously in the flank of 5–6 week old female SCID mice. From the day after implantation mice were fed a fat-free diet to which was added either 5 per cent (final diet weight) corn oil or 4 per cent EPA (as free acid) plus 1 per cent corn oil. Mice were killed before the tumour burden became excessive at around 3 weeks. Matched groups of animals without tumours were also studied.
Results: Mice fed the diet enriched with EPA had significantly smaller tumours than control animals [median 2810 mm^3 (interquartile range 2050–3790) versus 4960 mm^3 (range 3210–6320), $P=0{\cdot}023$]. Liver and spleens of tumour-bearing animals were substantially heavier than non-tumour-bearing controls ($P<0{\cdot}001$) due to metastases. Liver and spleens of tumour-bearing animals were significantly lighter in those fed EPA compared with those fed corn oil ($P<0{\cdot}001$) suggesting a reduced metastatic burden. As mice fed EPA ate significantly less food than controls (2·25 g/day versus 3·05 g/day, $P=0{\cdot}021$) and caloric intake will influence tumour growth in similar models, the experiment was repeated supplying matched amounts of food. Again tumours were smaller in EPA fed mice [3080 mm^3 (1800–3900) vs 4800 mm^3 (3060–6400), $P=0{\cdot}027$) and liver and spleens were lighter with EPA ($P<0{\cdot}02$) suggesting that tumour growth reduction was due to EPA and not diet restriction.
Conclusion: We conclude that 6–8 g/kg/day EPA within the diet will slow the growth of a human experimental tumour and reduce metastatic spread in a mouse model. The potential of EPA as a non-toxic anti-cancer agent deserves further study in human neoplastic disease.

Poster 051

Role of laparoscopy and laparoscopic ultrasonography in the surgical management of cholangiocarcinoma

K.K. Madhavan, E. Currie and O.J. Garden *University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh*

Background: This study aimed to evaluate the contribution of laparoscopy and laparoscopic ultrasonography in surgical decision making in the management of cholangiocarcinoma.
Method: Data on 35 patients who had laparoscopy and laparoscopic ultrasonography as part of their work up were collected retrospectively. The information provided by this investigation in addition to computed tomography (CT) scan and angiography was assessed.
Results: Of the 35 patients in the study, 22 had angiography and 31 had CT scans. Laparoscopy and laparoscopic ultrasonography predicted inoperability in 15 patients when CT and angiography had already suggested inoperability in seven of these. Of the remaining eight, five had peritoneal seedlings, two ascites and one had main portal vein involvement precluding curative surgery. Twenty-one patients (including one deemed irresectable on laparoscopic ultrasonography) underwent surgery. Curative resection could be achieved only in 13 patients (nine pancreatico duodenectomies, three hepatectomies and one bile duct resection). Laparotomy in the one patient, in whom laparoscopic ultrasonography suggested irresectability, confirmed irresectability and segment III cholangiojejunostomy was undertaken.
Conclusion: Laparoscopy contributes to the management of cholangiocarcinoma by excluding patients with peritoneal dissemination from unnecessary laparotomy. The additional information provided by laparoscopic ultrasonography does not add to the assessment of resectability — particularly local invasion for hilar cholangiocarcinomas where a Segment III cholangiojejunostomy provides the most effective surgical palliation.

Poster 052

Hepatic resection for colorectal cancer metastases

R.A. Carballo, J.L.A. Bastos, K. Yoong, B. Gunson, S. Brahmall, D.A.J. Mayer, P. McMaster and J.A.C. Buckles *The Liver Unit, Queen Elizabeth Hospital NHS Trust, Birmingham*

Background: This study aimed to assess the results of hepatic resection for colorectal cancer metastases.
Method: From 1986 to 1997, 86 consecutive patients undergoing liver resection for colorectal metastases with curative intent were studied. Fifty-one of them had major resections and 28 had minor resections. In 20 patients the liver secondaries were detected synchronously with the primary tumour. The other 66 had the liver involvement detected at a median of 21·2 months after resection of the primary colonic neoplasm. The liver was affected by single lesions in 55 patients and by multiple lesions in 32. The median size of the lesions was 6·1 cm and the median follow-up period was 23·9 months.
Results: The actuarial 1, 3 and 5 years survival for these patients was 75·4 per cent, 42 per cent and 26 per cent, respectively. The perioperative mortality rate was 2·3 per cent. There were no significant differences in the overall survival concerning the diagnosis of synchronous or metachronous metastases, nor in the number or size of the hepatic lesions when analysed as isolated parameters.
Conclusion: Liver resections for colorectal cancer metastases are relatively safe procedures and can offer the potential for prolonged long-term survival.

Poster 053

Lipiodol enhanced computed tomography scanning of liver tumours

R.A. Al-Mufti, E. Towu, R. Dick* and M.C. Winslet *University Departments of Surgery and *Radiology, Royal Free Hospital and School of Medicine, London*

Background: Lipiodol, an iodized poppy seed oil, is a contrast medium which has been shown to be taken up and retained selectively by primary and some metastastic liver cancers, following injection into the hepatic artery. This study aimed to assess the sensitivity of Lipiodol enhancement of computed tomography (CT) scanning of the liver in the diagnosis of liver tumours.
Method: Over a period of 6 years (1989–1995), all Lipiodol-enhancing CT scans of the liver were assessed retrospectively, and a grading classification was performed independently by a surgeon and a radiologist. Maki's grading of uptake of Lipiodol was carried out (grade IV = >90 per cent uptake, grade III = 50 per cent, grade II = 20–50 per cent, grade I = <10 per cent poor uptake). A total of 107 Lipiodol-enhanced CT scans were assessed. Hepatic angiography was carried out on all of these patients for diagnostic purposes, with intrahepatic arterial administration of 10 ml of Lipiodol emulsified in 10 ml of Urografin. A repeat Lipiodol CT scans of the liver were obtained 7–14 days after the intra-arterial injections of Lipiodol. A histological confirmation of the diagnosis was obtained for all the patients who were shown to have tumours on CT scanning.
Results: Forty-two patients were shown to have hepatocellular carcinoma, in whom Lipiodol-CT was diagnostic in 40. Nine patients had colorectal hepatic metastases (Lipiodol-CT was diagnostic in eight), and five patients were shown to have other metastatic tumours (Lipiodol-CT was diagnostic in all). Lipiodol-CT scans showed no uptake in normal or benign liver lesions, and was very helpful as a diagnostic tool. There was good correlation in the grading of Lipiodol uptake between the surgeon and the radiologist (98 per cent correlation). Patients with hepatocellular carcinoma showed a high degree of Lipiodol uptake, while the uptake and retention of Lipiodol in the patients with colorectal metastases was variable and inconsistent. Two liver transplant patients were shown to have early hepatomas.
Conclusion: Lipiodol-enhanced CT scanning is a valuable tool in detecting hepatocellular carcinoma and neuroendocrine tumours, with good uptake of Lipiodol (grade IV). The uptake in hepatic metasases of colorectal, renal and breast cancers is poor (grade II).

[Anti-17.1A × anti-CD3] F(ab′)$_2$ bispecific antibody inhibits growth of pulmonary metasteses in mice bearing syngeneic 17.1A-transfected tumour

J.C.J. Alberts, M.J. Glennie and J.A. Smallwood *Department of Surgery and Tenovus Research Laboratory, Southampton University Hospital, Southampton*

Background: Monoclonal antibody 17.1A confers a survival advantage on patients with high-risk colonic carcinoma and we have recently demonstrated that the bispecific F(ab′)$_2$ antibody heteroconjugate anti-17.1A × anti-CD3] can target human cytotoxic T lymphocytes against human colonic carcinoma *in vitro*. In the present study, we have examined the ability of T cells retargeted with an equivalent bispecific antibody to inhibit the growth of tumour in a murine model of metastatic disease.
Method: C57/BL mice were injected intravenously with syngeneic 17.1A-transfected B16 melanoma cells. Therapy with 17.1A immunoglobulin (IgG), [17.1A × CD3] F(ab′)$_2$ bispecific antibody and controls, was given both i.v. and i.p. on day 1 and i.p. daily for 9 days thereafter. Animals were killed on day 21. Their lungs were removed and the number of surface metasteses counted.
Results: Treatment with the bispecific F(ab′)$_2$ antibody derivative proved to be more efficacious than therapy with 17.1A IgG and resulted in a marked and significant (more than two-fold) reduction in the mean number of pulmonary metastatic deposits in that group of animals (mean number of tumour metasteses 59 cf. 157; $P<0.05$). Moreover, there was a highly significant reduction in the mean number of metastic deposits in mice treated with the bispecific heteroconjugate compared with controls (59 cf. 435; $P<0.005$) and therapy with 17.1A IgG compared with controls (157 cf. 435; $P<0.02$). Neither the bivalent anti-17.1A Fab′$_2$ nor anti-CD3 Fab′$_2$ therapy resulted in any measurable reduction in tumour burden when compared with the other treatment groups.
Conclusion: The [17.1A × CD3] bispecific, with equal specificity to the parent immunoglobulin, but a unique ability to selectively recruit killer effector cells, can inhibit tumour growth *in vivo* and may prove an attractive adjuvant in high-risk colorectal cancer.

Poster 055

A randomized, blinded trial of home versus hospital administered phosphate enema as flexible sigmoidoscopy preparation

J.N. Lund, D. Buckley, A.M. Smith, C. Maxwell-Armstrong, G.M. Tierney and J.H. Scholefield *Department of Surgery, University Hospital, Nottingham*

Background: Preparation for flexible sigmoidoscopy is often achieved by administration of a phosphate enema by nursing staff in the endoscopy department, which is time consuming and often embarrassing for patients. This blinded, randomized trial aimed to compare adequacy of preparation and acceptability of home versus hospital-administered enema.
Method: Consecutive patients having flexible sigmoidoscopy were randomized to receive a phosphate enema as bowel preparation either in the endoscopy department or to self-administer the enema at home. Adequacy of preparation was recorded on a scale of 0 to 10, according to the percentage of mucosa visible. Operators were blinded to whether the enema was given at home or in hospital. After the examination patients were asked to complete a questionnaire on the ease of preparation.
Results: One hundred and twenty consecutive patients were recruited. Of the 56 patients offered home preparation 25 declined to self-administer the enema. Intubation to the descending colon or more proximally was achieved in 88, 88 and 84 per cent of those randomized to hospital preparation, declining and accepting home preparation, respectively. Bowel preparation scored 8·21 ± 1·72 (mean ± SD) in those patients randomized to hospital enema, 8·40 ± 2·02 in those declining home preparation and 9·19 ± 1·01 in patients self-administering the enema at home. There were no complications of flexible sigmoidoscopy during the study. Home enema patients often stated that they found home preparation easier or less embarrassing than previous hospital-administered enema.
Conclusion: Preparation of the left side of the colon is equally good whether the enema is administered by a nurse in the endoscopy department or by the patients themselves at home. Home preparation may lead to time and cost savings and be more acceptable to many patients.

Poster 056

Topical and oral diltiazem lower the resting anal sphincter pressure

E.A. Carapeti, M.A. Kamm and R.K.S. Phillips *Department of Physiology, St Mark's Hospital, Harrow, Middlesex*

Background: This study aimed to investigate the effect of oral and topical diltiazem on lowering the resting anal sphincter pressure and to ascertain the most effective dosage and formulation.
Method: Two separate studies were conducted. In one study 10 subjects were given a placebo tablet followed by 60 mg diltiazem. Anal sphincter pressure and blood flow were measured before and 1 h after each tablet. Similar measurements were taken before, and 4 days after, once daily and twice daily regimens of diltiazem. In the second study diltiazem gels of increasing concentration were applied topically to the anus in 10 volun-

teers to determine the dose which most effectively lowers the resting anal sphincter pressure.
Results: 60 mg diltiazem lowered the mean resting anal sphincter pressure by 20 cm H_2O (21 per cent) compared to the pre-treatment value ($P = 0{\cdot}001$), whilst placebo was associated with a negligible 3 per cent decrease in the mean resting pressure ($P = 0{\cdot}09$). Once daily diltiazem produced no notable clinical effect whilst twice daily dosing reduced the mean anal pressure by 17 per cent ($P = 0{\cdot}008$). Two subjects noticed postural dizziness with this regimen. Topical diltiazem produced a dose-dependent reduction of resting anal pressure. A maximal effect was produced by 2 per cent diltiazem gel which lowered mean resting anal pressure by 28 per cent ($P < 0{\cdot}0001$), the effect lasting 3–5 h after a single application. Higher concentrations produced no additional effect. No side-effects were reported with topical diltiazem.
Conclusion: Both oral and topical diltiazem lower the resting anal sphincter pressure in healthy volunteers. Topical diltiazem seems both superior and safer than oral, with no side-effects encountered. It may therefore have a potential value in the treatment of anal fissures.

Poster 057

The efficacy of faecal diversion alone for extensive Crohn's disease

T. Yamamoto, I.M. Bain, R.N. Allan and M.R.B. Keighley
Department of Surgery and Gastroenterology, Queen Elizabeth Hospital, Birmingham

Background: This study was to assess the efficacy of faecal diversion alone for extensive Crohn's disease. Furthermore, we examined whether it is possible to predict which patients will respond to it.
Method: Medical records of 39 patients who underwent faecal diversion alone for extensive Crohn's disease were reviewed.
Results: Faecal diversion alone (loop ileostomy: 33, loop sigmoid colostomy: 6) was attempted in 24 patients with extensive colorectal disease (10 with severe anal disease, and five severe small bowel disease). Nine patients (23 per cent) have gone into complete remission and have had no further surgery for Crohn's disease with a mean follow-up of 94 months, and among these nine patients, five underwent closure of ileostomy or colostomy. Nine patients (23 per cent) achieved remission for more than 24 months after faecal diversion, 12 (31 per cent) relapsed between 6 and 24 months, and nine (23 per cent) were not improved at all and required operation for Crohn's disease within 6 months. There were no patient characteristics which identified those who would enter long-term remission.
Conclusion: These data indicate that faecal diversion alone may have a profound effect in achieving remission in a few patients with Crohn's disease, but it is impossible to predict the outcome.

Poster 058

Risk factors for anastomotic recurrence after ileocolonic resection for Crohn's disease

T. Yamamoto, I.M. Bain, R.N. Allan and M.R.B. Keighley
Department of Surgery and Gastroenterology, Queen Elizabeth Hospital, Birmingham

Background: This study was undertaken to investigate the factors that influenced the risk of anastomotic recurrence after ileocolonic resection for Crohn's disease.
Method: One hundred and forty-seven patients who underwent primary ileocolonic resection (ileocaecal resection or right hemicolectomy) between January 1980 and December 1995 were reviewed. Risk analysis was performed using Cox proportional hazard model and recurrence rates using Kaplan–Meier life-tables analysis.
Results: Only two factors emerged as being significantly related to anastomotic recurrence, these were: short duration of disease of less than 1 year prior to surgery (hazard ratio 4·23, $P = 0{\cdot}0005$) and smoking (hazard ratio 2·31, $P = 0{\cdot}002$). Age at onset of disease, sex, family history of Crohn's disease, perioperative corticosteroid therapy, emergency operation, type of disease (perforating/non-perforating), length of resected small bowel, length of resected large bowel, presence of granuloma in the specimen, involvement at the line of resection, or postoperative complications had no influence on anastomotic recurrence.
Conclusion: Short history of disease and smoking habit are important risk factors for anastomotic recurrence after ileocolonic resection for Crohn's disease.

Poster 059

Pruritus ani: experience from a combined colorectal and dermatological clinic

S. Dasan, S.M. Neill, D.R. Donaldson and H.J. Scott
Departments of General Surgery and Dermatology, St Peter's Hospital, Chertsey, Surrey

Background: The aim of this study was to establish the cause of pruritus ani in a group of patients referred to a combined colorectal and dermatological clinic and determine the most appropriate treatment.
Method: Forty patients with pruritus ani were seen in a combined clinic over a 6-month period. Assessment was by history, completion of a general health questionnaire, full examination of the skin, digital rectal examination, proctoscopy, sigmoidoscopy and patch testing. Patients were treated according to clinical findings at assessment.
Results: Thirty-four patients (84 per cent) had a recognizable dermatosis, three (8 per cent) had superficial perianal fissuring and three (8 per cent) had a normal perineum; two cases (5 per cent) required surgical intervention. Twenty-two patients (55 per cent) had positive reactions when patch tested. All patients have shown an improvement or complete resolution of their symptoms with treatment.
Conclusion: This series has shown that the majority of patients presenting with pruritus ani have a dermatosis as the underlying cause of their symptoms and that many of them have developed contact sensitivities to the various topical medications used. These findings suggest that referral to a dermatologist in the first instance may be more appropriate.

Poster 060

Repair of multiple colonic perforations using skin staples in lieu of sutures

D.P. Edwards, K.A. Galbraith and P.E. Watkins *Medical Countermeasures, CBD Porton Down, Salisbury, Wiltshire*

Background: Serosally placed skin staples have been used in lieu of sutures to reduce the time taken to construct small intestinal and colonic anastomoses. This study evaluated the healing of experimental colonic perforations repaired with either skin staples or sutures, in the presence of peritonitis.
Method: At laparotomy 12 colonic perforations were created in the spiral colon of pigs ($n = 24$). After 6 h peritoneal lavage was performed and the perforations were closed, six by local excision and single-layer suture closure, and six by inversion and closure with skin staples. Animals were killed either immediately after repair, at 5 days or at 14 days. The integrity of repairs was assessed by intraluminal pressure testing at post-mortem.
Results: The time to complete the stapled repairs was significantly less than that for sutured repairs (mean ± SD time (minutes) for stapled repairs: 5·0 ± 2·1; for sutured repairs: 29·4 ± 4, $P < 0{\cdot}001$, ANOVA). Mean ± SD leak pressures (mmHg) of the repairs were:

	Group 1 (6 h, $n = 6$)	Group 2 (day 5, $n = 8$)	Group 3 (day 14, $n = 10$)
Stapled	225·3 ± 59·0	247·3 ± 54·3	177·6 ± 26·4
Sutured	193·2 ± 46·7	220·9 ± 71·2	183·4 ± 31·9

There was no significant difference in the leak pressures between repair techniques at any time point.
Conclusion: Colonic repair using either skin staples or sutures can be performed with safety in the presence of faecal peritonitis. The use of skin staples in lieu of sutures reduces operating time without reducing the biomechanical strength of the healing colonic wounds.

Poster 061

Defunctioning loop ileostomy: a worthwhile procedure

G.C. O'Toole, D.C. Grant, M.K. Barry and J.M.P. Hyland *The Coloproctology Unit, St Vincent's Hospital, Elm Park, Dublin*

Background: Defunctioning loop ileostomies are an uncommonly utilized form of faecal diversion. The aim of this study was to determine the morbidity associated with both construction and reversal of loop ileostomies.
Method: An analysis was performed of all patients undergoing loop ileostomy construction or reversal between 1990 and 1997.
Results: One hundred and two patients (43 male, 59 female) with a mean age of 38 (range 13–81) years had a loop ileostomy constructed. Indications for ileostomy construction included inflammatory bowel disease (76 patients), low anterior resection for carcinoma (16 patients) or miscellaneous reasons (10 patients). Nine patients (9 per cent) had complications arising from ileostomy construction including four parastomal infections, three high output ileostomies, one small bowel obstruction and one ileostomy stenosis in the early postoperative period. Only the stricture required surgical intervention. All other complications settled with conservative management. Mean time to ileostomy reversal was 16 weeks. Three patients (4 per cent) had complications associated with reversal. All of these complications required surgical intervention, two for small bowel obstruction, one for small bowel perforation. Currently 81 patients have had their ileostomy reversed, and 16 patients have had their loop ileostomy converted to a permanent stoma for reasons not related to the loop ileostomy itself.
Conclusion: Defunctioning loop ileostomy is associated with low morbidity. We recommend a defunctioning ileostomy as the procedure of choice for temporary faecal diversion.

Poster 062

A selective policy for surgery in rectal prolapse

A.J. Brown, R.F. McKee and I.G. Finlay *Department of Coloproctology, Glasgow Royal Infirmary, Glasgow*

Background: Abdominal fixation for prolapse produces low recurrence rates but poor function. Rectopexy gives constipation; resection rectopexy may increase incontinence. Perineal operations are minimally invasive but have a high recurrence.
Method: We report 149 patients (133 females), mean age of 64 (±15) years with a median follow-up of 4 (0–9) years where surgery was selected on the basis of symptoms and general health. There were no operative deaths. Results shown below.
Results:

	Abdominal fixation	Perineal operation
No. patients	100	47
Prolapse recurrence	2 (2%)	8 (17%)
Constipation	51 (51%)	8 (17%)
Incontinence	52 (52%)	27 (57%)
Normal function	25 (25%)	6 (13%)

Conclusion: These data confirm that abdominal fixation is effective in preventing recurrent prolapse. Long-term functional results, however, are disappointing despite a selective policy; this may be related to the underlying pathophysiology of rectal prolapse.

Poster 063

The dose response of the internal anal sphincter to topical application of glyceryl trinitrate cream

J. Gunn, A. Varma, J.R.T. Monson and G.S. Duthie *Academic Surgical Unit, Castle Hill Hospital, Hull*

Background: Nitric oxide has been identified as an inhibitory neurotransmitter in the smooth muscle of the internal anal sphincter. The use of the nitric oxide donor glyceryl trinitrate in the treatment of high pressure anal disease such as anal fissure has created a great deal of interest. The dose response of the IAS to topical application of GTN cream, however, is still not clear. The aim of our study was to define the dose response to topical GTN on the IAS.
Method: A double-blind placebo-controlled dose-ranging study was carried out to compare the effect of three different concentrations of GTN cream (0·1, 0·2 and 0·4 per cent) on the IAS. Forty-eight patients were randomized and underwent ambulatory anorectal manometry using a two-port solid-state manometry catheter and ambulatory data logger. Patients had baseline manometry recorded for 1 h and then 1 ml of cream was applied to the anal canal. Patients underwent ambulatory anorectal manometry and recorded daily activities on an events diary. After 24 h the patients returned and the catheter was removed if not displaced by defecation. Data were down loaded and adverse events were recorded. Recordings were visually analysed for changes in mean anal pressure (MAP).
Results: Mean resting anal pressure for pre- and post-GTN treatment in cm H_2O is given below.

	Placebo	GTN 0·1%	GTN 0·2%	GTN 0·4%
Number	11	13	12	13
MAP Pre Rx	71·2	72·1	76·5	77·2
MAP Post Rx	64·2	56·00	54·5	50·2
GTN vs Placebo		$P=0·087$	$P=0·006$	$P=0·004$

Only three patients reported a mild transient headache on GTN application, these were distributed in all active treatment groups.
Conclusion: There is a significant drop in resting anal pressure after the application of GTN cream in all groups compared to placebo which appears to be related to concentration of GTN. In conclusion, the internal anal sphincter demonstrates a dose-related response to the application of the nitric oxide donor glyceryl trinitrate.

Poster 064

Laparoscopic-assisted mobilization of the gracilis muscle for dynamic anal neosphincter formation

J. Gunn, R. Farouk, J. Hartley, K. Heer and G.S. Duthie *Academic Surgical Unit, Castle Hill Hospital, Hull*

Background: The gracilis dynamic neosphincter performed as a two- or three-stage procedure is becoming increasingly established as a means of restoring continence in patients with end-stage faecal incontinence. Early morbidity is primarily due to sepsis, lead displacement or muscle/tendon failure. Morbidity due to long leg wound associated with gracilis mobilization is often described. We describe laparoscopic mobilization of the gracilis muscle as a modification of the gracilis dynamic neosphincter procedure.
Method: A 36-year-old woman underwent this modified procedure. Under general anaesthesia with hip joint in external rotation a 5 cm incision was made over the medial aspect of thigh 5–8 cm distal to pubic tubercle. A 10 mm Psion laparoscope with a 0 degree end-viewing lens allowed visualization of distal muscle mobilization with laparoscopic scissors without insufflation. Haemostasis was achieved by diathermy. A visiport with the laparoscope inserted for visualization was used to

complete distal dissection through a separate 2 cm incision. The rest of the procedure was done as per the standard technique of the surgeon. The laparoscopic section of the procedure took 62 min to perform and rest of the procedure, wrap and insertion of leads took 45 min. The patient mobilized 8 h after surgery.
Conclusion: We believe that gracilis can be mobilized safely by laparoscopic dissection. By using this approach, avoidance of a long leg wound with its attendant morbidity and early mobilization of the patient is possible.

Poster 065

ras pathways in colorectal cancer

J.V.T. Tilsed, H.J.N. Andreyev, D. Cunningham and P.A. Clarke
CRC Centre for Cancer Therapeutics, Institute of Cancer Research and The Royal Marsden Hospital, Surrey

Background: The ras genes are key mediators of signal transduction controlling cellular proliferation and differentiation and between 25 and 50 per cent of colorectal cancers have been shown to have mutations in the Kirsten-ras gene which give rise to a constituatively active ras protein. This study was performed to examine whether other abnormalities of ras protein activation are present in colorectal cancers that do not have a Kirsten-ras mutation: in particular of growth factors and their receptors that signal via the ras pathway.
Method: Sections of 105 consecutive early colorectal cancers were obtained. DNA was extracted and mutations at codons 12 and 13 of the Kirsten-ras gene identified by direct sequencing. Immunohistochemical staining was used to identify expression of ras proteins, the growth factors EGF and TGF-α, and their common receptor, EGF-R.
Results: Of 105 colorectal cancers, 30 had activating mutations of the Kirsten-ras gene, 92 had high levels of ras protein, 84 produced excess EGF and 20 TGF-α, while 78 overexpressed EGF-R. Production of EGF and TGF-α were not mutually exclusive: 17 tumours produced both. EGF-R expression did not occur in isolation: 72 (92·3 per cent) also had high levels of ras protein and 71 (91 per cent) produced excess growth factor. There was no difference in growth factor, EGF-R or ras protein expression between wild-type tumours and those with Kirsten-ras mutations. However, a ras pathway abnormality was identified in over 95 per cent of the tumours.
Conclusion: ras pathway abnormalities are present in almost all colorectal cancers and may offer a suitable target for therapeutic intervention.

Poster 066

Long-term continence and pelvic floor injury

R.C. Bollard, A. Varma, S. Lindow and G.S. Duthie *Academic Surgical Unit, Castle Hill Hospital, Hull*

Background: Obstetrically damaged anal sphincter is the principal cause of faecal incontinence in otherwise healthy women. The aims of this study were to assess the long-term outcome of obstetric pelvic floor injury. The incidence of faecal incontinence symptoms overall was 6·3 per cent and for urinary symptoms 8·2 per cent at 1 year.
Method: Obstetric and physiological data were prospectively collected in 159 women. We have reviewed the long-term symptomatic outcome of these patients at 1 year by questionnaire and physiological assessment correlated to postnatal scan.
Results: Ninety-nine out of the 159 replied (62 per cent). Of these patients, three (1·88 per cent) had new symptoms of faecal urgency, four (2·5 per cent) incontinence of flatus and two (1·25 per cent) incontinence of solid motions. Six (3·77 per cent) had new symptoms of urinary urgency, three (1·88 per cent) suffered with urinary stress incontinence and six (3·77 per cent) had urge incontinence of urine.

Endoanal scan result		Persistent new symptoms at 1 year		
Abnormal	15	Faecal	$n=2$	33·3%
		Urinary	$n=4$	26·6%
Normal	144	Faecal	$n=8$	3·47%
		Urinary	$n=9$	6·25%

Two patients had persistently low resting anal pressures and maximum squeeze pressures at 1 year, both had confirmed ruptured sphincters. One of these patients had incontinence of flatus and also urinary urge incontinence; the other was asymptomatic at 1 year.
Conclusion: The high-risk pelvic floor can be predicted by postnatal endoanal ultrasonography.

Poster 067

Hand-held manometry: a useful tool in the outpatient department

R.C. Bollard, A. Varma, A. Gardiner and G.S. Duthie *Academic Surgical Unit, Castle Hill Hospital, Hull*

Background: Does hand-held anal manometry transducer compare reliably with the standard pressure transducer used in the physiology department? Can the hand-held manometer be used as a convenient tool in the outpatient setting to avoid the need for a visit to the specialist anorectal physiology laboratory?
Method: Twenty-four patients were examined, four resting pressure recordings were recorded by each of the single channel hand-held pressure transducer (Gaeltec Ltd, Skye) and the dual channel pressure transducer with ambulatory box recorder MPR2 (Gaeltec Ltd, Skye) used routinely in the anorectal physiology laboratory. Maximum voluntary and involtunary pressures were also recorded.
Results: A total of 192 resting pressure recordings were analysed. Although individual records of pressure were not identical between the two groups, there was good correlation between corresponding hand and laboratory transducer readings per patient and between mean resting pressure readings. Maximum voluntary and involuntary pressures also correlate strongly (Spearman/Kendall non-parametric correlation and paired samples correlation).
Conclusion: The hand-held transducer is repeatable, and as good as the physiology laboratory equipment in measuring resting anal pressures. It is therefore useful in the outpatient department and as a research tool; avoiding the need for some patients to attend the anorectal physiology laboratory.

Poster 068

Expression of transforming growth factor beta polypeptides in colorectal cancer

D.R. West, E. Anderson, R.D. James, N.J. Haboubi and S.T. O'Dwyer *Paterson Institute, Withington, Manchester*

Background: Increased levels of the inhibitory peptide transforming growth factor beta 1 (TGFβ 1) in colorectal and other tumours are, paradoxically, predictive of poor prognosis. The aim of the present study was to determine the prognostic value of the TGFβ receptor (TGFβR2) and another TGFβ isoform (TGFβ 3).
Method: Expression of TGFβR2 and TGFβ3 was detected in 106 paraffin-embedded formalin-fixed colorectal tumour samples, by incubating three μ sections with either polyclonal anti-TGFβR2 (R&D Systems AF-241-NA) or anti TGFβ3 (R&D Systems AB-244-NA) antibodies after microwave retrieval. Specific antibody binding was detected with a biotinylated secondary antibody followed by an ABC peroxidase system (Vector Laboratories) using diaminobenazidine as substrate. The sections were counterstained with haemotoxylin. Cytoplastic staining was scored negative, positive or borderline when compared to control sections treated with a normal goat IgG instead of primary antibody.

Results: The survival analysis calculated using the Kaplan–Meier method is shown in the figure below.

	Negative staining		Positive staining		Borderline staining
Antibody	% of samples	median survival (weeks)	% of samples	median survival (weeks)	% of samples
Anti-TGFβR2	47	115	37	130	16
Anti-TGFβ3	37	99	54	112	15

Analysis of the survival curve showed that the presence of TGFβR2 ($P = 0{\cdot}82$) or TGFβ3 ($P = 0{\cdot}91$) was not predictive of survival.

Conclusion: Insenstivity to TGFβ1 is thought to be due to loss of signal transduction via the TGFβR2 and TGFβ3 has been shown to protect epithelial cells from cytotoxic and radiation damage. However, we could not demonstrate a correlation between the presence of TGFβR2 and TGFβ3 and survival in our cohort of colorectal tumours.

Poster 069

Crypt cell proliferation state in the human colon. Validation of results obtained by whole crypt microdissection and the findings in patients with familial adenomatous polyposis, sporadic adenomas and colorectal cancer

S.J. Mills*†, J.C. Mathers*, P.D. Chapman**, J. Burn** and A. Gunn† *Departments of *Biological and Nutritional Sciences and **Human Genetics, The University of Newcastle upon Tyne, and †Wansbeck District General Hospital Trust, Ashington*

Background: This study aimed to establish the validity of mitosis counts following whole crypt microdissection as an index of the crypt cell proliferative state (CCPS). To examine the effect of normal biological variables (age, sex and colonic site) and colonic neoplasia on the mitotic index in macroscopically normal human colon.

Method: Mucosal samples were obtained at colectomy or colonoscopy from 109 individuals (26 controls, 23 sporadic adenoma patients, 31 sporadic carcinoma patients and 29 patients with familial adenomatous polyposis [FAP]). The specimens were hydrated, hydrolysed and small groups of crypts separated from the main specimen under a dissecting microscope. The total number of mitoses/crypt were counted by one observer for each of 10 complete crypts.

Results: Validation work established that whole crypt mitoses counts were reliable and reproducible. There was no relation between age and mean mitoses/crypt (Pearson correlation coefficient −0·1). The CCPS count was higher for males than for females (M:F = 6·7:3·9, $P = 0{\cdot}008$) amongst the controls (but there was no gender difference in the three disease groups). The mean mitoses/crypt were similar for the controls and adenomas (5·6 and 4·7, respectively) but greater for the cancers and FAP (8·3 and 14·2, respectively). Statistical analysis confirmed that there were significant differences ($P < 0{\cdot}05$) between controls and all disease groups together, between sporadic disease and FAP and between adenoma and carcinoma subjects at each of the four colonic sites. For all disease groups and controls the crypt mitotic count showed a significant linear increase ($P \leq 0{\cdot}004$) from the rectum to the caecum. Biopsies from within 5 cm of the macroscopic margin of a carcinoma (near) gave a mean mitosis count of 12·6 whilst those from more than 10 cm (far) were lower but not significantly so ($P = 0{\cdot}12$) with a count of 9·0.

Conclusion: Whole crypt microdissection and mitosis counting is a reliable, reproducible and robust technique for assessing CCPS in the human colon. CCPS is unaffected by age, but increases from distal to proximal colon. CCPS is increased if a sporadic cancer is present and markedly increased in FAP. However, the precise relation of an increased CCPS to the neoplastic process remains uncertain.

Poster 070

Mesorectal excision for rectal cancer in a district general hospital

M.I. Booth and T.C.B. Dehn *Royal Berkshire Hospital, Reading, Berkshire*

Background: The aim of this study was to assess the results of mesorectal excision for rectal cancer in a district general hospital.

Method: All patients undergoing excisional surgery for rectal cancer under one surgeon from June 1991 to June 1997 reviewed retrospectively and partly prospectively.

Results: Eighty-one patients (45 male) with a mean age of 65·4 (range 38–87) years. Sixty-five procedures potentially 'curative' (i.e. no macroscopic residual disease/no perforation). Forty-one performed by the consultant and 24 by a higher surgical trainee assisted by the consultant. Forty-seven were anterior resections (30 defunctioned), 14 abdomino-perineal excisions, two Hartmann's, two procto-colectomies. All with mesorectal excision. Dukes' stage A 12 (18 per cent); B 22 (34 per cent); C 31 (48 per cent). Fifteen had preoperative radiotherapy, eight postoperative radiotherapy and 15 postoperative chemotherapy. Thirty-day mortality 3 (4·6 per cent). Clinically evident anastomotic leaks 3 (4·6 per cent), all in defunctioned anastomoses with no mortality/major morbidity. Of the 62 survivors in the 'curative' group, two (3·2 per cent) developed isolated local recurrence at 23 and 24 months postoperatively. Six developed distant recurrence (combined with local recurrence in one) at a mean of 16·7 months postoperatively (8–30 months). Mean follow-up 24·5 months (4–81).

Conclusion: Mesorectal excision for rectal cancer produces a low incidence of local tumour recurrence. It can be safely practised in the district general hospital setting by supervized higher surgical trainees.

Transplantation

Poster 071

Results of renal transplantation in Indo-asian recipients

C.M. Richardson, P.C. Butterworth, J.F. Feehally and M.L. Nicholson *Department of Surgery, Leicester General Hospital, Leicester*

Background: In contrast to the results of renal transplantation into black recipients, the results of renal transplantation into Indo-asian recipients performed in the developed world have not been well studied. This unit serves a region with a large Indo-asian population and we have compared the results of renal transplantation in this group with those in our white population.

Method: Data were retrieved from our existing transplant database and by retrospective review of the case notes on all cadaveric transplants performed in the 9-year period to 31 December 1996. The results of transplantation in 49 Indo-asian recipients and 245 white recipients have been compared using non-parametric tests.

Results: There were no differences in median donor age (40 years for Indo-asians versus 41 years for whites, $P = 0{\cdot}88$), median recipient age (48 years versus 47 years, $P = 0{\cdot}68$), total number of mismatched antigens at HLA A,B and DR loci ($P = 0{\cdot}16$), median cold ischaemic time (23 h versus 20 h, $P = 0{\cdot}19$), or median anastomosis time (34 min versus 34 min, $P = 0{\cdot}97$). Postoperatively, immunosuppression was by cyclosporin-based dual therapy or triple therapy or by tacrolimus-based therapy in a small number of recipients. The quality of initial graft function was similar in both populations, with delayed graft function rates of 20 per cent versus 22 per cent and initial function rates of 80 per cent and 74 per cent for Indo-asians and whites, respectively. The incidence of acute rejection (biopsy confirmed) in the first 6 months was 29 per cent for Indo-asians and 37 per cent for whites ($P = 0{\cdot}35$). Rejection episodes were less commonly steroid resistant in Indo-asians than in whites but this difference just fails to reach statistical significance (5 per cent versus 16 per cent,

$P=0{\cdot}08$). Renal function as measured by median serum creatinine (µmol/l) was better in Indo-asians than in whites at 6 months, 1 year, 2 years and 5 years (140 versus 154, $P=0{\cdot}04$; 141 versus 155, $P=0{\cdot}05$; 133 versus 163, $P=0{\cdot}02$; 116 versus 157, $P=0{\cdot}002$). However, there was no difference in the graft survival between the two populations: 1 year 88 per cent for Indo-asians versus 81 per cent for whites, 2 years 83 per cent versus 77 per cent, 3 years 71 per cent versus 75 per cent, 4 years 64 per cent versus 70 per cent, 5 years 64 per cent versus 65 per cent.
Conclusion: We conclude that the results of renal transplantation into indo-asian recipients are at least as good as those in white recipients.

Poster 072

The brachiobasilic fistula is superior to prosthetic grafts for secondary vascular access

P.C. Butterworth, T.M. Doughman and M.L. Nicholson
Department of Surgery, Leicester General Hospital, Leicester

Background: Patients requiring long-term haemodialysis often require multiple operations in order to maintain their vascular access. The options for secondary access procedures become increasingly limited as superficial veins become unavailable. Prosthetic grafts are commonly used in difficult cases but their use is associated with a high incidence of complications.
Method and Results: We have used the brachial artery-transposed basilic vein arteriovenous fistula in preference to prosthetic grafts in 31 cases where the superficial veins were not available. There have been no technical failures and 28 (90 per cent) of these fistulas have developed sufficiently to enable dialysis. No major infections have occurred. Three fistulas have been electively ligated because of steal phenomena or oedema. Two fistulas thrombosed but one was salvaged by thrombectomy and more proximal anastomosis. At median follow-up of 12 months, 24 fistulas remain patent. Prosthetic grafts have been used on 23 occasions since 1990. In four cases prosthetic conduits were used because the basilic vein was inadequate when explored. Three grafts could not be needled successfully. Fourteen grafts have thrombosed. Ten of these underwent emergency thrombectomy but flow was only successfully restored in nine. Eight grafts have become infected and have been removed. Three patients have died with functioning grafts. Grafts with 1 year follow-up ($n=16$) show only 43 per cent patency.
Conclusion: The encouraging results with the brachiobasilic arteriovenous fistula and the very disappointing results with prosthetic grafts suggest that, in difficult cases, the brachiobasilic fistula should be fashioned in preference to using prosthetic conduits wherever possible.

Upper Gastrointestinal

Poster 073

Cost effectiveness of laparoscopic surgery for gastro-oesophageal reflux disease

E. Ahmed, B. Decadt and M. Gray *South Kent Hospitals*

Background: We studied our first 31 sequential patients undergoing laparoscopic Nissen fundoplication. In-theatre and in-hospital costs were calculated, based on £400 per hour and £150 per day, respectively. The cost of preoperative drug treatment was calculated, based on an annual cost of £460 per annum for 20 mg Omeprazole and £350 for 10 mg Cisapride t.d.s.
Method: Fifteen men and 16 women, mean age 45 (range 18–73 years). Median preoperative history of GORD 5 years (1–30 years). There were no conversions to open operation, no re-operation and no major complications. One patient was readmitted with recurrent symptoms within 1 week.
Results: Median in-hospital stay was 3 nights (range 1–8 nights). Median in-theatre time was 75 (range 50–180) minutes. Mean cost of in-patient care was £1300. Mean drug use 40 mg omeprazole; cost £921 per annum. Thirty of the 31 patients were able to abandon all anti-reflux medication postoperatively. The median De Meester symptom scores improved from 7 preoperatively to 1 postoperatively (range 9–1).
Conclusion: On this cost basis, cost of laparoscopic Nissen fundoplication is recouped within 18 months of operation, a significant saving on the NHS drug budget.

Poster 074

Helicobacter pylori in patients with familial adenomatous polyposis

M. Wallace, A. Forbes and R.K.S. Phillips *ICRF, St Mark's Hospital, Harrow*

Background: Almost all patients with familial adenomatous polyposis (FAP) develop duodenal adenomas and approximately 5 per cent of these will go on to develop upper gastrointestinal cancer. The aim of this study was to detect the presence or absence of *Helicobacter pylori* in the gastric antrum of patients with FAP and document any association with of duodenal polyposis as *H. pylori* has been implicated in foregut neoplasia.
Method: Fifty FAP patients underwent upper gastrointestinal endoscopy. Biopsies of the gastric antrum were sent for histology and CLO test. An assessment of degree of duodenal polyposis was made.
Results: The median age was 40 years (range 22–66 years, 34 males). *H. pylori* was found in eight patients (16 per cent). In the patients greater than 40 years of age (30) significantly fewer were colonized with *H. pylori* than an age matched, asymptomatic group of the general population ($P<0{\cdot}01$). There was no correlation between degree of duodenal polyposis and presence or absence of *H. pylori*.
Conclusion: The incidence of *H. pylori* found in FAP patients was less than that of the asymptomatic general population. This may be related to the differences in the bile of these patients which may be having an inhibitory effect on the rate of *H. pylori* colonization. *H. pylori* does not seem to be implicated in their duodenal tumourigenesis.

Poster 075

Gastrostomy tube and button insertion at initial endoscopy

C.C. Hepworth*†, A.E. Stuart†, W.R. Burnham‡ and C.P. Swain*
**GI Science Research Unit, St Bartholomew's and The Royal London School of Medicine and Dentistry, London, and Oldchurch †Surgical and ‡Medical Gastroenterology Departments, Romford, Essex*

Background: Endoscopic placement of a trocar and split sheath allows placement of either a gastrostomy tube or button, but tenting of the gastric mucosa hinders placement of the trocar. The aim of this study was to minimize the tenting effect.
Method: Following insufflation of the gastric cavity with a gastroscope a hollow cannula was placed directly into the gastric cavity (through the anterior abdominal wall) and a polydiosanone (PDS) thread passed down the cannula. Another cannula was placed 2–3 cm away through which a loop was passed. The PDS was placed through the nylon loop. The loop was closed and withdrawn with both cannulae through the anterior abdominal wall. Traction on the PDS lifted up both the abdominal wall and anterior aspect of the stomach. This allowed the trocar to be placed with a stab technique between the two threads. Postmortem porcine gastric studies ($n=10$) were performed to assess the amount of displacement of gastric mucosa with and without the PDS thread. Then the trocar and split sheath was inserted with a stab technique on a live porcine stomach ($n=10$).
Results: Postmortem studies showed: 1) displacement of gastric mucosa was significantly less ($P<0{\cdot}0001$, Mann–Whitney) when the PDS (median displacement was −0·5 cm, range −0·5 cm to 0·5 cm) was used than when no thread was used (median displacement 5 cm, range 3 cm to 5·5 cm). Traction on the gastric mucosa that is applied when a suture is used

results in a negative tenting effect; 2) the trocar was successfully placed in 100 per cent cases with the PDS but only in 50 per cent of occasions without PDS due to tenting ($P = 0.03$, Fisher's Exact test); 3) live porcine studies confirmed the easy placement of the trocar and split sheath with minimal tenting. This allowed placement of either a gastrostomy tube or button.

Conclusion: Placement of a trocar and split sheath is facilitated with this method allowing gastrostomy tubes and buttons to be placed at the initial endoscopy.

Poster 076

Helicobacter pylori and recurrence of ulcer-like pain after highly selective vagotomy

S. Kumar, S. Ghosh and I.M.C. Macintyre *Western General Hospital NHS Trust, Edinburgh*

Background: This study aimed to assess the association of *Helicobacter pylori* and recurrence of ulcer-like pain after highly selective vagotomy (HSV) for duodenal ulcer.

Method: A cohort of 433 patients who have had HSV in the last 6–23 years after HSV were asked to complete a questionnaire about their current symptoms and medication and offered 13C urea breath test for detection of *H. pylori*.

Results: Two hundred and twenty-seven patients, 175 men and 52 women, who have had HSV in the past (median age 38 years; range 18–66 years), replied to the questionnaire and undertook the 13C urea breath test. The urea breath test detected *H. pylori* in 146 patients (64·3 per cent). There were 83 patients (37 per cent) who experienced pain on most days or every day, or needed to take omeprazole, H_2 receptor antagonists or antacids on most days or every day. Fifty patients were positive for *H. pylori* and 33 were negative for *H. pylori*. The difference is statistically significant ($P < 0.0001$, Independent t-test).

Conclusion: *H. pylori* infection is present in 64·3 per cent of patients after HSV and may play a significant role in recurrence of ulcer-like pain.

Poster 077

Adenocarcinoma of oesophagus junction and cardia: similar response to neo-adjuvant therapy

E.D. Mulligan, T. Purcell, B. Dunne, M. Griffin, N. Noonan, D. Hollywood, N. Keeling, J.V. Reynolds and T.P.J. Hennessy *Department of Surgery, Pathology and Gastroenterology, St James' Hospital, Dublin*

Background: There has been a major recent increase in the incidence of adenocarcinoma of the lower oesophagus, oesophago-gastric junction (OGJ) and gastric cardia, and it is unknown whether these tumours have a common aetiology and molecular tumourigenesis. Moreover, with multimodal approaches to therapy becoming standard for oesophageal adenocarcinoma, we set out to determine whether tumours of the OGJ and cardia respond similarly to multimodal therapy.

Method: We studied 63 patients with adenocarcinoma at these sites undergoing multimodality treatment (two cycles of fluorouracil and cisplatin and 40 Gy of external beam radiation). We classified patients as either responders (pathological T0N0-1, T1N0-1 or T2N0) or non-responders (T2N1 or T3N0-1).

Results:

	Cardia $n = 15$	OGJ $n = 24$	OES $n = 24$	
Responders	47%	58%	46%	$P = 0.64$
Complete pathological response	13%	33%	8%	$P = 0.07$
Nodes positive	27%	13%	38%	$P = 0.132$
3-year survival	33%	33%	25%	$P = 0.78$

Conclusion: There was no significant difference between the three tumour locations in terms of response to multimodal therapy, nodal status or survival, lending support to the thesis that these tumours share a common biology. Moreover, the inclusion of tumours from these three sites in trials of multimodality therapy appears valid.

Poster 078

Screening for gastric carcinoma using *Helicobacter pylori* serology

J.B. Davies, S. Everett, M. Wilcox, H.M. Sue Ling, A.T.R. Axon and D. Johnston *Centre for Digestive Diseases, The General Infirmary, Leeds*

Background: *Helicobacter pylori* infection is associated with a 3–4 fold increased risk of developing gastric carcinoma. It has been suggested that it may be possible to select patients who are at greater risk of gastric cancer for early endoscopy by serological testing for *H. pylori*. We wished to determine the prevalence of *H. pylori* infection, determined by two serological kits to maximize sensitivity, in patients presenting with gastric carcinoma in a University Teaching Hospital.

Method: One hundred and thirty-eight consecutive patients attending the surgical department from October 1990 to 1995 with gastric carcinoma (proven histologically) had 10 ml whole blood taken either preoperatively or no later than 2 weeks postoperatively. *H. pylori*-specific IgG assays were performed using both the Pylori Elisa II (BioWhitaker) and Premier *H. pylori* (Launch) enzyme-linked immunosorbent assay (ELISA) kits.

Results: We studied 138 patients with a median age of 70 years. Overall, the Launch kit was positive for *H. pylori* in 103 cases (74·6 per cent), and the BioWhitaker kit was positive in 84 cases (61 per cent; 10 cases equivocal). Concordance between kits was 81·9 per cent. If either kit was positive, 105 were *H. pylori*-positive giving a maximum sensitivity for detection of carcinoma of 76·1 per cent. The prevalence of *H. pylori* did not increase significantly in younger patients (21 of 28, 75 per cent patients aged <60 years versus 84 of 110, 76·4 per cent aged >60 years), in lower and mid-third tumours compared with upper third (42 of 55, 76 per cent; 19 of 26, 73 per cent; and 34 of 43, 79 per cent, respectively) or according to tumour stage (21 of 26, 80·7 per cent stage I; 9 of 14, 64·3 per cent, stage II; 38 of 43, 88·4 per cent stage III; and 37 of 55, 67·3 per cent stage IV, $P = 0.06$). Of the 33 patients that were negative for *H. pylori* on both kits, four had had previous gastric surgery and one had family history of gastric cancer, but no other risk factors could be identified.

Conclusion: At least 20 per cent of our carcinoma patients were negative for *H. pylori* using two ELISA kits. This approach cannot be recommended for prioritization of the investigation of dyspepsia.

Poster 079

Laparoscopic port site recurrence of cancer: a system of classification

K.S. Zayyan and D.P. Sellu *Surgical Sciences, Imperial College School of Medicine, Hammersmith Hospital, London*

Background: The absence of a method of classifying port site recurrences (PCR) makes it difficult to collate and compare cases for descriptive, therapeutic and prognostic purposes. We attempted to provide a simple but practical classification based on the published case reports.

Methods: Through an extensive literature search and personal contacts, we identified 120 cases of PSR. We developed and sent a questionnaire to the authors, inquiring about details of the operation, the PSR and outcome of further intervention, without identifying case or source.

Results:

Type	Features
Type I	One PSR, usually at the port of specimen extraction or the working port. No other recurrences (13·0% of reported cases)
Type II	IIa One PSR plus a resectable intraperitoneal recurrence, usually in the vicinity of the bed of the resected viscus (e.g. paracolic gutter or gallbladder fossa). No peritoneal disease on first look procedure, no other recurrences on second (4·3%) IIb More than one PSR plus a resectable intraperitoneal recurrence (17·4%)
Type III	One or more PSRs in a patient with unresectable peritoneal nodules with or without ascites on second look only. No peritoneal disease on first look (34·8%)
Type IV	Any number of PSRs in a patient with unresectable disease (ascites, hepatic metastasis, carinomatosis peritonei) on first look (30·4%)

Conclusion: We believe this classification provides a useful framework for describing and comparing recurrences based on presentation and resectability. All 42 cases we have collected so far fall within these categories but 'atypical' cases may occur that warrant a slight modification to the above classification.

Poster 080

Rapid reduction of CO_2 causes laparoscopic aerosolization of free cancer cells: evidence from a new rat model

K.S. Zayyan, D.P. Sellu, R.T. Mathie, J.S. Christie-Brown, S. Van Noorden and C.Y. Yiu* *Imperial College School of Medicine, Hammersmith Hospital, London, and *Whittington Hospital, London*

Background: The mechanism of port site recurrence (PSR) following laparoscopy is unknown although the insufflatant is thought to contribute. We developed a new animal model to test the hypothesis that rapid reduction was more likely to aerosolize free cancer cells than slow reduction or gasless laparoscopy.
Method: We developed a novel portless gas reduction valve and randomized 55 Fischer rats into rapid reduction (RR, to receive 20 L CO_2 at 0·67 L/min, $n=20$), slow reduction (SR, 20 l at 0·44 L/min, $n=20$) and gasless control groups (GL, $n=15$). In half of the animals in each group (non-recovery) immunolabelled rat colon cancer cells (RCC2) were used and harvested peritoneal and port specimens examined by flow cytometry (FC) and fluorescence microscopy (FM) while in the other half (recovery) viable, unlabelled RCC2 were used and animals killed at 4 weeks.
Results: Nine of ten non-recovery RR animals had RCC2 on FM or FC compared to two in each of the SR and GL groups ($P=0·018$, Fisher's exact test). Two recovery RR animals developed PSR at 4 weeks compared to zero in the other groups ($P=0·315$).
Conclusion: In this simple model, dispersal of free cancer cells occurred by aerosolization during rapid reduction. This disseminated tumour into the general peritoneal cavity but was not a significant cause of PSR.

Poster 081

Gastric cancer in the over 80s: is radical surgery justified?

S.P.L. Dexter, J.B. Davies, G.V. Miller, I.G. Martin, H.M. Sue Ling and D. Johnston *Department of Surgery & Centre for Digestive Diseases, The General Infirmary, Leeds*

Background: This study aimed to evaluate the outcome for patients over 80 years of age following surgery for gastric cancer.
Method: All patients who were diagnosed or treated for gastric cancer over a 5-year period (1990–1995) at our institution were reviewed. The results for patients over 80 years of age were analysed.
Results: Eighty-nine patients with gastric cancer over the age of 80 were identified (median age 82·8 years, range 80·2–92·6). Forty-seven (53 per cent) of these patients underwent a surgical procedure. Operative procedures included potentially curative (R0) resection (43 per cent), palliative (R1 or R2) resection (43 per cent), surgical bypass (9 per cent) or laparotomy/laparoscopy only (6 per cent). After potentially curative resection, in-hospital mortality appeared to be lower for patients operated on by the specialist upper GI team (2 of 13 patients) than by other surgical teams (3 of 7 patients) although this was not statistically significant (χ^2 $P=0·15$). Median survival of the whole group (89 patients) was 0·62 years. The overall survival for patients who underwent R0 resection by the upper gastrointestinal team was 58 per cent, 48 per cent and 19 per cent at 1, 2 and 3 years, respectively, with a median survival of 1·7 years.
Conclusion: Patients of advanced age can benefit from radical and potentially curative surgery for gastric cancer with acceptable perioperative mortality. Good results require careful case selection and preoperative staging and preferably treatment within a specialist unit.

Poster 082

Are patients with bleeding or perforated peptic ulcers being tested for *Helicobacter pylori*?

R. Jones, M.R. Lansdown and T.A. Wright *Department of Surgery, St James University Hospital, Leeds*

Background: It is recommended that patients who have had surgery for bleeding or perforated peptic ulceration are tested for *Helicobacter pylori* in order to prevent further complications. Because it is often impractical to perform endoscopic antral biopsies either pre- or postoperatively, we have looked to see if these patients are actually being tested.
Method: From 1991 to 1997 all patients having surgery for bleeding or perforated peptic ulcer disease were identified from the operating theatre data base and the notes reviewed. Patients were sent questionnaires to determine symptoms.
Results: We found 83 patients with a mean age of 58 years (range 20–96 years); 51 of 61 patients were men. Only 21 of 83 patients were tested for *H. pylori*. Only 3 of 26 patients taking non-steroidal anti-inflammatory drugs (NSAIDs) and 2 of 13 patients who had an acid reducing operation were tested for *H. pylori*. Four patients were treated blindly. Patients were more likely to be tested if they were still experiencing symptoms but we found that 50 per cent of patients had been asymptomatic prior to the perforation or haemorrhage. Even after excluding patients on NSAIDs, who had acid reducing surgery, who were tested or had blind treatment, there were still 24 patients who could still benefit from *H. pylori* testing.
Conclusion: It is likely that a significant proportion of these patients are inadequately investigated and treated to prevent the risk of further complications.

Poster 083

The prognostic value of laparoscopic ultrasound identified lymph node status for patients with upper gastro-intestinal malignancy

M.E. Flett, D.M. Bruce and K.G.M. Park *Department of Surgery, Aberdeen Royal Infirmary, Aberdeen*

Background: We have previously shown that laparoscopy, combined with high frequency, high resolution ultrasound scan is a safe technique which improves staging of gastro-oesophageal malignancy when compared to conventional techniques (clinical, endoscopy, abdominal ultrasound and computed tomography [CT] scan). The aim of this study was to examine the impact on tumour recurrence and patient survival of intra-abdominal lymph node status as identified by laparoscopic ultrasound (LUS).
Method: Forty-four patients who had tumours, which were deemed resectable by the conventional staging modalities outlined above, and who underwent LUS, were available for follow-up. Of these, 37 had proceeded to resection and seven were managed by palliative therapies having been 'upstaged' by LUS. Data regarding LUS nodal staging, tumour recurrence

and patient survival were prospectively collected. All patients have been reviewed until death or at least 1 postoperative year. Nodal group comparisons are between tumours staged N0 compared with N1 or 2 by UICC criteria (1992).

Results: The overall group had a 58 per cent 1 year cumulative survival (median 14 months; standard error [SE] 0·08). However, those patients proceeding to resection had 67 per cent 1 year survival (median 17 months [SE 6]) which was much greater than the group that underwent palliative therapies, with no 1 year survivors (median 4 months [SE 6]). LUS-defined nodal status predicted no significant difference in survival of the overall group or gastric/oesophageal subgroups. However, there was a trend towards prolonged survival in the node-negative group (median 29 months; SE 9 in the node-negative group compared with 13 months; SE 4 in the positive group). Disease-free survival was greater in LUS node-negative patients (26 months [SE 2] compared with 13 months [SE 4], $P < 0·005$).

Conclusion: LUS staging allows us to predict the likelihood of recurrence of gastro-oesophageal malignancies. This may prove a useful tool for the appropriate allocation of patients to primary and adjuvant therapies

Poster 084

An independent prospective audit of ruptured abdominal aortic aneurysms (AAA) in Wales

P.S. Basnyat, S. Shiralkar, A. Biffin, R. Hedges and M.H. Lewis *On behalf of the Surgeons and the All Wales Audit Resource Unit from East Glamorgan General Hospital, Mid Glamorgan*

Background: The aim of this study was to identify the incidence and mortality of ruptured abdominal aortic aneurysms (AAA) in Wales.

Method: All patients presenting to hospital with confirmed AAA rupture in Wales between September 1996 to February 1997 have been studied. Data were collected prospectively by the All Wales Audit Resource Unit observing strict confidentiality.

Results: Ninety-seven patients (64 men) with ruptured AAA were identified. Abdominal pain ($n = 55$), back pain ($n = 35$) and shock ($n = 71$) were the commonest presenting features. Associated risk factors included previous myocardial infarction ($n = 16$), angina ($n = 24$), hypertension ($n = 37$), stroke ($n = 13$), diabetes ($n = 7$) and smoking ($n = 29$) at the time of rupture. Sixty patients were referred from the accident and emergency department, 26 were referred directly by GPs. Eight were interdepartmental referrals and in three patients the route of referral was unknown. Fifty-eight patients were investigated by ultrasound/computed tomography scan prior to treatment. Twenty-five patients died without an operation (three dead on arrival, six in casualty and 16 unfit for operation). Operation was performed in 72 patients. Of those, 53 patients died within 30 days following operation. Complications following surgery included cardiac ($n = 14$), respiratory ($n = 12$), renal ($n = 6$) and stroke ($n = 1$).

Conclusion: Operative mortality was 74 per cent and the overall mortality for ruptured AAA reaching hospital in Wales was 80 per cent. Screening for AAA is probably the only way forward to improve these results.

Poster 085

The hidden hazards of blood transfusion during abdominal aortic aneurysm (AAA) repair: a comparison of autologous and homologous products

S.P. Cavanagh, S. Estdale, A. Rawstron, S. Noblett, M.J. Gough and S. Homer-Vanniasinkam *The Vascular Surgical Unit, The General Infirmary, Leeds*

Background: Cell-savers are increasingly used during AAA repair allowing autologous transfusion of red blood cells (RBC) in saline. However, the infusate may contain other constituents of whole blood and inadvertent transfusion of white cells, activated neutrophils (polymorphonuclear neutrophils [PMN] [$\times 10^9$/L]), lymphocytes (lymph), monocytes (mono), cytokines (interleukin [IL]-1, IL-6, IL-8, tumour necrosis factor alpha [TNFα] [pg/ml]), and lipid mediators (LTB_4 [pg/ml]) could promote a systemic inflammatory response syndrome.

Method: Thus levels of these mediators were measured in 10 patients during AAA repair, in the infusate from a cell-saver and in 10 units of homologous packed-cells (values are medians and interquartile ranges).

Results:

	Patient	Infusate	Packed cells
WBC	5·55 (4·60–7·10)	5·65 (4·70–6·15)*	7·20 (5·90–8·55)†
PMN	4·40 (3·38–5·42)	4·25 (4·05–4·95)	2·30 (0·75–3·55)*†
Mono	0·14 (0·09–0·16)	0·14 (0·10–0·21)	0·80 (0·60–1·40)*†
Lymph	1·20 (0·91–1·32)	0·90 (0·62–1·65)	4·90 (3·60–6·20)*†
CD11b	160 (132–256)	538 (353–1131)*	875 (689–938)*
CD18	117 (105–131)	194 (148–228)*	199 (153–210)*†
L-selectin	59·6 (46·8–61·5)	51·8 (35·3–74·8)*	232 (157–241)*†
LTB_4	7·15 (4·20–10·55)	264 (129–480)*	56 (36·5–164)*†
IL-6	20·15 (17·75–24·85)	39·05 (24·25–100)*	4·65 (4·60–5·0)*†
IL-8	1·00 (0·25–3·00)	10·50 (5·10–27·05)*	14·00 (9·65–26·00)*

*$P < 0·0001$ versus patient, †$P < 0·0001$ packed cells versus infusate, minimal IL-1 and TNF-α detected in both products.

Conclusion: The infusate contains activated PMN (increased CD11b and CD18 expression, L-selectin shedding), monocytes and lymphocytes, and increased levels of LTB_4, IL-6 and IL-8. Theoretically the transfusion of these factors may be deterimental. Although similar results were obtained from homologous packed cells this contained greater numbers of cytokine producing monocytes and lymphocytes. This, and the other clinical advantages of autologous blood transfusion, favour the continued use of cell-saver devices.

Poster 086

The cytokine response to controlled reperfusion during limb salvage surgery

S.P. Cavanagh, A. Rawstron, M.J. Gough and S. Homer-Vanniasinkam *The Vascular Surgical Unit, The General Infirmary, Leeds*

Background: Neutrophils (PMN) promote ischaemia-reperfusion injury (IRI) and PMN depletion by both mechanical and immunological methods has been shown to ameliorate this injury in animal models. However, thus far leucodepletion has not been subjected to clinical assessment.

Method: In 10 patients undergoing limb salvage surgery, the effect of PMN depletion (using a double lumen femoral venous catheter, extracorporeal circuit, leucocyte filter, and flow rates of 200 ml/min for 15 min [3000 ml or ~60 per cent blood volume filtered]) upon levels of interleukin (IL)-6, IL-8 and tumour necrosis factor alpha (TNFα) were compared with the same measurements in 10 control patients undergoing similar surgery (CP). Samples were taken from both peripheral (PER) and femoral (FEM) venous blood at baseline, reperfusion (T_0), 4 h, 24 h, 3 and 6 days (T_4, T_{24}, T_{3D}, T_{6D}).

Results: Except at baseline, levels of IL-6 were lower in the filter patients (FP) at all time points. These differences (expressed as percentage changes from baseline, median and interquartile ranges) were significant at T_0FEM (FP versus CP: +122 per cent versus +148 per cent, $P < 0·0001$), T_0 PER (FP versus CP: +15 per cent versus 52 per cent, $P < 0·0001$), T_{3D} (FP versus CP: +79 per cent versus +444 per cent, $P = 0·0256$), T_{6D} (FP versus CP: −24 per cent versus +221 per cent, $P = 0·0457$). TNFα levels were higher in FP, particularly at T_0 PER (FP versus CP: −15·7 per cent versus −16·8 per cent, $P < 0·0001$) and T_4 PER (FP versus CP: −9 per cent versus −43 per cent, $P < 0·0001$). Levels of IL-8 were lower in the PER samples [T_0(FP versus CP: +1·8 per cent versus +4·1 per cent, $P < 0·0001$), $P < 0·0001$), T_{24}(FP versus CP: +2 per cent versus +125 per cent, $P < 0·0001$)] but higher in FEM samples [T_4(FP versus CP: +24 per cent versus +5 per cent, $P < 0·0001$) T_{24}(FP versus CP: +72 per cent versus +49 per cent, $P < 0·0001$)] of filtered patients.

Conclusion: This study of intraoperative PMN depletion showed changes in the cytokine profile that would be consistent with amelioration of IRI. Thus levels of the PMN-dependent pro-inflammatory cytokine IL-6 were reduced, whilst those of IL-8 in femoral blood increased (leucocyte adhesion inhibition effect). Similarly peripheral TNFα levels were higher and this should suppress PMN release from bone marrow reserves. The incidence of infective complications, amputations and death were comparable in the two groups. This technique appears safe, and its therapeutic role warrants further investigation.

Poster 087

An evaluation of the elastic properties of *in situ* human umbilical vein grafts

M.J. Tighe, S.W. Galloway, R. Lea and J.F. Clegg *Department of Surgery, Leighton Hospital, Crewe*

Background: Compliance mismatch between an artery and graft leads to a region of excessive mechanical stretch with endothelial injury and flow disturbance. These factors are known to be involved in the development of intimal hyperplasia around anastomoses, with associated implications on graft patency. The aim of this study was to determine the elastic properties of the human umbilical vein (HUV) graft *in vivo* and compare them with the recipient's vessels (artery proximal and distal to the anastomosis).

Method: Forty grafts used for femoropopliteal bypass were assessed by duplex imaging with simultaneous blood pressure monitoring. Distension and diameter of the vessel or graft with a certain pressure change were used to calculate relative distension (RD), distensibility coefficient (DC), and compliance coefficient (CC). Data are expressed as median with interquartile range.

Results:

	Proximal artery	HUV graft	Distal artery
RD (%)	4·58 (2·48–6·85)	5·6 (3·4–10·95)	4·7 (2·35–8·90)
DC (10^{-3}/kPa)	9·75 (5·62–14·40)	13·00 (8·45–24·65)	9·2 (5·05–21·80)
CC (mm^2/kPa)	0·94* (0·43–1·77)	0·55 (0·34–0·70)	0·37 (0·19–0·61)

*$P<0·01$ when compared with graft or artery using Mann–Whitney U-test.

There was no significant difference between the RD or the DC, between the host artery and the HUV graft. The HUV graft was then compared with a series of 12 patients with *in situ* saphenous vein grafts and no significant difference in RD, DC or CC was found between the two groups ($P=0·42$).

Conclusion: This study demonstrates the elastic properties of the HUV graft *in situ*. It has similar properties to native artery and *in situ* saphenous vein grafts and may therefore have theoretical advantages over other prosthetic conduits.

Poster 088

Prevalence of visceral artery disease in patients undergoing renal revascularization

M.S. Sobeh, G.O. Hellawell, T. Watkinson and G. Hamilton
The Vascular Unit, The Royal Free Hospital, London

Background: The choice of renal revascularization procedure is influenced by the site of the stenosis, the patency of the contralateral renal artery and the presence of visceral artery disease, particularly of the coeliac axis. In this study, we reviewed the prevalence of contralateral renal artery stenosis, superior mesenteric artery stenosis and coeliac axis stenoses in patients who had undergone renal revascularization.

Method: The angiograms of 122 patients (57 renal angioplasties and 65 anatomic and extra-anatomic bypasses performed between 1992 and 1997) were reviewed.

Results: All patients had renal artery stenosis of greater than 50 per cent. Renal artery occlusion was present in 30 per cent of patients, 10 per cent were bilateral. The prevalence of contralateral renal artery stenosis (>50 per cent) was 64 per cent. Stenoses in either the superior mesenteric artery (SMA) or coeliac axis (CA) were present in 67 per cent of these patients. Stenosis on the CA were the most frequent (60 per cent of all patients). Stenoses of all four vessels (both renal arteries, SMA and CA) were present in 23 per cent.

Conclusion: This study demonstrates the frequent co-existence of coeliac axis and contralateral renal artery stenoses. Screening of all visceral vessels with lateral views of the origins of both SMA and CA is recommended for the appropriate choice of renal revascularization procedure.

Poster 089

Endovascular stents in aortoiliac disease: a single centre experience

S. Nawaz, T. Cleveland, P. Gaines and P. Chan *Sheffield Vascular Institute, Northern General Hospital, Sheffield*

Background: This study aimed to evaluate the initial and late results of intravascular stenting for atherosclerotic occlusive disease of the aortoiliac region and to determine potential predictive factors of stent failure and success.

Method: The preprocedural clinical records, ankle:brachial pressure index (ABPI), duplex and angiographic data were assessed on 140 patients (162 limbs) who underwent primary or secondary stent placement for lesions in the common iliac (55 per cent) or external iliac (45 per cent) artery, either for an occlusion (61 per cent) or stenosis (39 per cent). Initial and late success was assessed by restoration of femoral pulse, Fontaine score and ABPI and, where available, by duplex and angiography. A further cohort of patients at 1 year underwent duplex assessment.

Results: Clinical follow-up data (mean 18 months) were available for 125 patients (93 per cent). In this cohort improvement at last follow-up was determined by: Fontaine criteria (71 per cent); patient reported claudication distance (89 per cent) and ABPI measurement (97 per cent). Primary patency as assessed clinically, for occlusions was 90 per cent at 1 year and 89 per cent at 18 months and for stenoses was 94 per cent at 1 year and 94 per cent at 18 months. Absent femoral pulses were restored in all cases ($n=100$). Technical problems included failure to place stent, eight cases (4·4 per cent), unsatisfactory stent placement, 13 cases (8 per cent) and persistent gradient, 16 cases (10 per cent). Early complications occurred in seven patients (4 per cent) and included one death, two episodes of distal embolization, one amputation and three cases of thrombosis. Late complications of stent restonosis and occlusion occurred in 13 patients (8 per cent) and one case of stent migration. More occlusive lesions (9/100) were subject to late complications than stenoses (4/62). Other significant factors included lesions of the common iliac artery, persistent gradient, incorrect placement, continued smoking, not on antiplatelet agents and male gender ($P<0·05$ χ^2). Use of multiple stents favoured long-term patency ($n=20$, $P<0·05$).

Conclusion: Stenting of the iliac arteries is safe and durable stenting can be equally applied to occlusions as well as stenoses with similar early and immediate results, and only a slightly increased incidence of late failure.

Poster 090

Quality control during endovascular aortic surgery: role of sac pressure and lower limb Doppler measurements

I.M. Loftus, M.M. Thompson, N. Lennard, J. Smith, G. Treharne, G. Fishwick and P.R.F. Bell *Department of Surgery, University of Leicester, Leicester*

Background: Endovascular aneurysm repair is associated with technical failure of stent deployment in up to 10 per cent of cases. The aim of this study was to employ direct measurement of the aneurysm sac pressure and Doppler flow monitoring of the superficial femoral artery (SFA) to ensure complete exclusion of the aneurysm from the circulation.

Method: An angiographic catheter was passed via an ilio-femoral conduit into the aneurysm sac of 14 consecutive patients undergoing endovascular aorto-uni iliac repair. This catheter was connected to an external pressure transducer allowing pressure monitoring during, and for 24 h post-procedure. Flow was monitored in the SFA by insonation with a 2 MHz Doppler ultrasound probe.
Results: No technical defect was observed in the deployment of 9 of 14 stents where there was marked reduction in sac pressure and good flow in the lower limb (results show the median and range of aneurysm sac pressure as a percentage of systolic blood pressure):

	Pre-deployment	Post-deployment	Completion	24 h postoperative
Pressure	112 (95–124)	57 (35–86)	42 (34–75)	55 (27–76)

In five cases technical problems were detected by the monitoring process. In three cases incomplete stent deployment was detected by a rise in sac pressure to systolic pressure after balloon deflation. In a further two cases the aneurysm sac pressure rose towards completion. Poor SFA flow was detected in one and contrast injected into the aneurysm sac revealed incomplete iliac occlusion, requiring open ligation. The second had good SFA flow and contrast injection revealed large patent lumbar vessels. Contrast injection at 24 h revealed complete exclusion of the sac. Two patients required conversion to open repair.
Conclusion: Monitoring aneurysm pressure in combination with SFA Doppler flow can detect complications of endovascular aneurysm repair which can be corrected intraoperatively.

Poster 091

Thrombelastography: an effective screening test for prothrombotic states

A. Handa, D.J. Cox, K.J. Pasi, D.J. Perry and G. Hamilton
Royal Free Hospital, London

Background: A proportion of the population have an inherited thrombotic tendency predisposing to fatal thromboembolic disorders. Their investigation is expensive and often only undertaken in specialist centres. Thrombelastography (TEG) is a method of global haemostasis testing. It is a cheap, easy test to perform. Over 15–30 minutes a characteristic tracing is developed from measuring the strength of the clot as it forms.
Method: One hundred and three consecutive patients who were attending for investigation of a suspected prothrombotic state were analysed by TEG in addition to standard thrombotic screening tests. TEG results were blindly analysed and stratified into normal, hypocoaguable, hypercoaguable or borderline. Comparison was made of the interpretation of the two sets of results (TEG versus thrombotic screening tests).
Results:

	TEG results			
Blood test results	Normal	Hypocoaguable	Hypercoagulable	Borderline
Normal	31	3	10	8
Abnormal	0	4	15	16
Anticoagulants	0	16	0	0

All patients normal on TEG were found to be normal on thrombotic screening. Twenty of 23 (87 per cent) identified as hypocoagubale had an identifiable cause, either warfarin therapy or factor XII deficiency. Thirty-one of 49 (63 per cent) patients identified as borderline or hypercoaguable had a defined prothrombotic abnormality. Eighteen patients were shown to be hypercoaguable or borderline by TEG but no prothrombotic abnormality was found.
Conclusion: The TEG is a simple and rapid test to perform. Patients identified as hypercoaguable or borderline merit formal investigation for an underlying prothrombotic abnormality. A normal TEG obviates the need for formal investigation in approximately one third of patients

Poster 092

Outcome following stenting for aortoiliac occlusive disease

A.S. Atwal, G.O. Hellawell, A. Handa, N. Tai, A. Platts*, A. Watkinson*, D.M. Baker and G. Hamilton *University Department of Surgery, and *Radiology, Royal Free Hospital, London*

Background: The aim of this study was to determine the outcome of patients undergoing stent insertion for aortoiliac occlusive disease.
Method: Thirty patients who had stent insertion over 3 years were reviewed. Eight patients underwent stenting of bilateral lesions, giving a total of 38 lesions treated. Twenty-two lesions were treated for claudication, 16 for critical limb ischaemia (10 rest pain, six ulcers and two gangrene). Indications for stenting were complete occlusion (22), severe primary stenosis (15) and restenosis (1). Thirty of the lesions were in the common iliac, and eight in the external iliac artery. There were 13 Palmaz, 13 Wallstents, 10 Memotherm and two Symphony stents inserted.
Results: There were two early stent occlusions, at day 2 and day 7, both in patients with critical limb ischaemia. Both these patients required eventual limb amputation (1 above knee amputation, 1 below knee amputation). One patient died of respiratory failure on day 15 after stent insertion unrelated to the stenting procedure. There were two groin haematomas. Adjunctive procedures included thrombolysis in one patient, percutaneous angioplasty distal to stent insertion in two patients and infra-inguinal bypass grafting in four patients. One patient required embolectomy due to a complication of stent insertion. Thirty-one of the 38 stents (82 per cent) were patent at mean follow-up of 12 (range 1–33) months.
Conclusion: Stenting for iliac occlusive disease can be performed with acceptable early complication rates. Early patency rates are encouraging.

Poster 093

Elective repair of type IV thoraco-abdominal aortic aneurysms: experience with a subcostal transabdominal approach

M.J. Brooks, A. Bradbury and J.H.N. Wolfe *Department of Vascular Surgery, St Mary's Hospital and Imperial College Medical School, London*

Background: Univariate analysis of preoperative factors in 74 type IV thoraco-abdominal aortic aneurysm (TAAA) repairs revealed that preoperative pulmonary function tests provided the only significant predictor of postoperative morbidity. A technique using a subcostal approach was first proposed in 1995. We now review the results of this technique with particular emphasis on outcome and changes in early postoperative pulmonary function.
Method: A single surgeon performed 62 elective type IV TAAA repairs from which full clinical and respiratory data was available in 35: 20 thoraco-laparotomy (Group I) and 15 transabdominal (Group II).
Results: The overall 30-day mortality was 11·4 per cent (four patients). No patient developed paraplegia or required long-term renal support. No significant differences were seen in age, weight, anaesthetic time or recorded blood loss between the two groups.

	Group I	Group II
Standardized preoperative PEFR	73%	80%
Standardized preoperative FEV1	83%	89%
Standardized preoperative FVC	92%	89%
ITU admission FiO2	0·45	0·58
ITU admission pO2 (kPa)	11·7 (6·5–28·6)	7·1 (7·3–24·8)
ITU admission pCO2 (kPa)	5·20 (4·1–7·2)	5·14 (3·7–8·8)
Intubation (h)	19	11
ITU stay (days)	2 (median)	4 (median)
Ward stays (days)	12 (median)	11 (median)

The only difference to reach significance was in ITU admission FiO2 ($P=0{\cdot}07$). Splenic injury (4 of 15 versus 2 of 20) and re-operation (5 of

15 versus 0 of 20) were more common in Group II patients. Weight was a significant predictor for re-operation in Group II patients ($P = 0{\cdot}05$).

Conclusion: The overall morbidity and mortality were acceptable. The higher rates of splenic injury and re-operation in the subcostal group suggest that they may have been presdisposed to by technical problems resulting from restricted access. The association between the likelihood of re-operation and weight is consistent with this view. Any benefit in improved respiratory function has been outweighed by an increase in complications, possibly the result of technical problems due to lack of good exposure.

Poster 094

Critical limb ischaemia in patients with end-stage renal failure

E.J. Sharp, C. Skidmore, D. Taube, N.J.W. Cheshire, A.O. Mansfield, G. Stansby and J.H.N. Wolfe *Department of Vascular Surgery, St Mary's Hospital and Imperial College Medical School, London*

Background: The study aimed to assess the mortality and limb salvage rate for critical ischaemia in patients with end-stage renal failure.

Method: Thirty-one patients with 37 critically ischaemic legs presented over 18 months; male:female ratio 22:9, mean age 63 (range 32–85) years. There were 21 diabetics (68 per cent), 24 patients on dialysis (77 per cent) and seven had a functioning renal transplant (23 per cent). Twenty-three patients (62 per cent) had rest pain, 21 (57 per cent) ulceration and 22 (59 per cent) gangrene.

Results: Arterial revascularization was performed in 23 of 37 legs (59 per cent). This included seven angioplasties, 14 infra-inguinal grafts (two above knee, five below knee and seven crural) and one graft thrombectomy. Successful limb salvage was achieved in 15 of 22 revascularized limbs (68 per cent) but four limbs required minor foot amputations at the time of surgery. The other seven required a major amputation (32 per cent), five below knee and one above knee. Fifteen out of 37 limbs (41 per cent) in 13 patients were unsuitable for revascularization. Of these, five had a minor foot amputation only and retained a functioning limb, two died with critical ischaemia and eight had a major amputation (seven below knee and one above knee). The 30-day mortality for these patients was 3 of 31 (10 per cent). During a mean follow-up of 8 months 7 of 31 patients died (23 per cent).

Conclusion: Primary amputation is more common in patients with critical limb ischaemia and end-stage renal failure, but for those in whom revascularization is undertaken the results are worthwhile for this severely handicapped group of patients.

Poster 095

The prevalence of cerebral computed tomography infarction in the asymptomatic carotid surgery trial in relation to carotid stenosis and prior contralateral symptoms

P. Robless on behalf of the ACST collaborators *Academic Surgical Unit, ICSM at St Mary's Hospital, London*

Background: The Asymptomatic Carotid Surgery Trial (ACST) has randomized over 1670 patients to determine if carotid endarterectomy prolongs stroke-free survival versus best medical treatment alone. This study aimed to determine the prevalence of hemispheric cerebral infarcts in relation to severity of ipsilateral carotid disease and prior contralateral symptoms.

Method: Patients with preoperative computed tomography (CT) were divided into groups with ipsilateral stenoses >80 per cent or <80 per cent and into groups with prior contralateral stroke, cortical transient ischaemic attack (TIA), amaurosis fugax or no symptoms.

Results: There were 1144 patients with preoperative CT and 170 patients with MR scans. Patients with bilateral carotid stenosis >80 per cent (41 of 524) by duplex had a higher prevalence of cerebral CT infarction (37 per cent versus 18 per cent, $P = 0{\cdot}03$) compared to patients with unilateral stenosis >80 per cent (483 of 524). Patients with unilateral stenoses >80 per cent (483 of 1609) had a higher prevalence of ipsilateral CT infarction (18 per cent versus 13 per cent, $P = 0{\cdot}01$) compared with unilateral stenoses <80 per cent (1126 of 1609). Those with prior contralateral stroke (134) had the highest prevalence of hemispheric CT infarcts (61 per cent). Those with TIA (122) had a 30 per cent prevalence of CT infarction. Prevalence of hemispheric CT infarcts was 18 per cent in patients with amaurosis fugax (45) and 10 per cent in those with no prior symptoms (758). The Mantel– Haenszel test for linear association was significant ($P < 0{\cdot}001$) for increasing severity of symptoms.

Conclusion: In the ACST, patients with bilateral or unilateral carotid stenosis >80 per cent had a higher prevalence of cerebral infarction. The prevalence of contralateral hemispheric infarction was proportional to the severity of prior contralateral symptoms.

Poster 096

A comparison of transcranial Doppler and transcutaneous cerebral oximetry to stump pressure measurements during carotid endarterectomy

P. Robless, T. Tegos, I. Williams, N.J.W. Cheshire, A.N. Nicolaides, A. Mansfield and G. Stansby *Academic Surgical Unit, ICSM at St Mary's, London*

Background: Transcutaneous cerebral oximetry (TCO) and transcranial Doppler (TCD) monitoring can be employed during carotid endarterectomy (CEA) to determine changes in cerebral perfusion during clamping. The aim of this study was to compare TCO and TCD with carotid stump pressure measurements.

Method: Thirty patients undergoing CEA were studied. Ipsilateral cerebral oximetry and TCD monitoring of the ipsilateral middle cerebral artery (MCA) were performed. After carotid clamping, the mean carotid stump pressure was measured. The percentage fall in MCA velocity and the fall in cerebral oxygen saturation were also recorded.

Results: Patients were divided into those with a stump pressure >50 mmHg (18) and those with ≤50 mmHg (12). The median fall in MCA velocity when stump pressure was >50 mmHg was 31 per cent. Median fall in MCA velocity when stump pressure was ≤50 mmHg was 51 per cent. There was a significantly larger fall in MCA velocity when stump pressure was ≤50 mmHg ($P = 0{\cdot}01$ Mann–Whitney U-test). The fall in MCA velocity inversely correlated with the ratio of stump pressure to mean arterial pressure (Spearman, $r = 0{\cdot}77$, 95 per cent CI: 0·90 to 0·48, $P < 0{\cdot}0001$). The fall in cerebral oxygen saturation was not associated with mean stump pressure ($P = 0{\cdot}2$). The fall in oxygen saturation was inversely correlated with the ratio of stump pressure to mean arterial pressure (Spearman, $r = 0{\cdot}55$, 95 per cent CI: 0·83 to 0·06, $P = 0{\cdot}03$). There were no postoperative neurological events in the study.

Conclusion: The measurement of MCA velocity by TCD may be a useful adjunct to stump pressure measurement in deciding when to use a shunt as well as for shunt monitoring. Cerebral oxygen saturation may not be as comparable, casting doubt on its usefulness in clinical practice.

Poster 097

Quantitative reflux measurements before and after surgical treatment of varicose veins

E. Kalodiki and A.N. Nicolaides *Vascular Department, Imperial College School of Medicine at St Mary's Hospital, London*

Background: The aim of the study was to determine the amount of reflux in limbs with incompetent veins both pre- and postoperatively in order to demonstrate effective treatment.

Method: Sixteen legs of 12 women with varicose veins were included in this prospective study. The level of the saphenofemoral junction ± the incompetent perforating veins were marked preoperatively with duplex scanning. The venous filling index (VFI) denoting the amount of reflux in

ml/s was measured by air-plethysmography (APG) the day before the operation and on day 1 and at 6 weeks postoperatively.
Results: With APG the mean amount of reflux preoperatively was 4·11 ml/s, (min 2·4; max 7·8). On day 1 postoperatively the VFI normalized (i.e. less than 2·0 ml/sec) in all but five patients (mean value 1·76 ml/s). At 6 weeks postoperatively the mean value of the VFI was 1·54 ml/s. In the two limbs that the VFI remained greater than 2 ml/s the preoperative values were 5·1 and 7·8 ml/s and were reduced to 3·9 and 2·4 ml/s, respectively. The first patient had additional short saphenous vein incompetence that was not corrected.
Conclusion: Air-plethysmography is a valuable test that quantifies the amount of reflux in ml/s preoperatively and could be used for the postoperative documentation of effective treatment of limbs with incompetent veins. This could be particularly valuable in patients with intractable ulcers and to monitor the long-term results of valvuloplasty operations.

Poster 098

Endovascular repair of abdominal aortic aneurysms: improved access with iliac arterial wallstents

A.S. Brown, J. Rose and M.G. Wyatt *Northern Vascular Centre, Freeman Hospital, Newcastle upon Tyne*

Background: Iliac arterial tortuosity and luminal narrowing can cause problems during insertion of bifurcated aortic stent grafts with possible limb occlusion. We aimed to review the effect of prophylactic iliac stenting on the outcome of abdominal aortic aneurysm (AAA) stent grafts and associated radiological exposure.
Method: Between December 1995 and October 1997, 40 patients underwent endovascular treatment of infrarenal AAAs. In all cases a bifurcated device was successfully deployed. Nine patients were noted to have an iliac stenosis or narrowing with significant tortuosity. Wallstents were placed in the iliac vessels of all nine patients (seven unilateral, two bilateral) prior to insertion of the aortic stent. Follow-up was by computed tomography at 1, 3, 6, 12, 18 months (median 6; range 1–21 months).
Results:

	Wallstent	No wallstent	*P*
Number	9	27	
Median fluoroscopy time	27 min	32 min	NS
Median contrast volume used	350 ml	290 ml	NS

Two early and two late iliac limb occlusions have occurred, none in the group pre-treated with wallstents. One early occlusion occurred during treatment of a proximal endoleak. The remaining three have all been associated with significant iliac angulation (>80°). There were no procedural deaths or conversion to open repair. One patient pre-treated with a wallstent died on day 6 from a myocardial infarct. Of the remaining eight patients, all have patent iliacs bilaterally, no endoleaks and no distal complications. Overall 30-day mortality = 5 per cent (11·1 per cent for the wallstent group).
Conclusion: A high proportion of bifurcated stent grafts will occlude at least one limb in the presence of iliac tortuosity or stenosis. Wallstents appear to decrease this occlusion rate without significantly increasing radiological time, allowing easier stent graft deployment.

Poster 099

The impact of aortic stenting on aneurysm mortality

A.S. Brown, S. Dugdill, M.J. Clarke, N.A.G. Jones, J. Chamberlain, J. Rose and M.G. Wyatt *Northern Vascular Centre, Freeman Hospital, Newcastle upon Tyne*

Background: Between 1988–1992, the perioperative mortality for elective abdominal aortic aneurysm (AAA) repair at this hospital was 3·9 per cent. Our aim was to examine the impact of an aortic stenting programme on mortality rates for patients undergoing elective AAA repair.
Method: Between December 1995 and September 1997, computed tomography (CT) and calibrating arteriography were used to select patients for aortic stent graft repair. Standard open repair was performed for those unsuitable for stenting. Results were recorded prospectively on a computerized vascular data base (BIPAS) and mortality compared.
Results:

	n	No. deaths	Perioperative mortality rate
Stent grafts	37	2	5·4%
Open repair	70	9	12·8%
Total	107	11	10·2%

Conclusion: The 30-day mortality for the repair of elective infrarenal AAAs has risen three-fold over the last 5 years but these figures reflect both alteration in referral patterns and patient selection for elective surgery. It is misleading to compare the results of aortic stenting with either historical or consecutive groups of patients undergoing open AAA repair. The true impact of aortic stenting on perioperative mortality will not be known until the results of multi-centre randomized prospective trials are available.

Poster 100

Are early results of abdominal aortic aneurysm stenting misleading?

A.S. Brown, S. Dugdill, J. Rose and M.G. Wyatt *The Northern Vascular Centre, Freeman Hospital, Newcastle upon Tyne*

Background: If abdominal aortic aneurysms (AAA) fail to decrease, or actually increase in size following stenting, there may still be a risk of rupture. Our aim was to examine early changes in AAA size following apparently successful aortic stenting.
Method: Forty AAAs have been repaired using a bifurcate system. The maximum aortic diameter was recorded for each patient on preoperative computed tomography (CT). Follow-up scans have been performed at regular intervals (0, 1, 3, 6, 12 and 18 months). All scans have been examined for endoleak and change in AAA diameter. Patients have been grouped dependent upon initial AAA size (Group 1, 45–54 mm; Group 2, 55–64 mm; Group 3, >65 mm).
Results: Two patients died prior to discharge. Thirty-three patients have reached 1 month follow-up (median 6 months; range 1–21 months). Changes in AAA diameter are shown as percentage of the immediate postoperative measurement (giving median values and ranges).

	Group 1	Group 2	Group 3
Number of patients	11	14	8
Median follow-up (months)	6	6	6
% diameter change	−4·3% (−28·8 to +1·5)	−2·4% (−30 to +8·3)	−2·4% (−15·6 to +4)

Since stent insertion, 20 aneurysms have decreased, seven increased and six remained unchanged in size. Two aneurysms have increased by greater than 5 per cent but neither has an endoleak evident on CT.
Conclusion: Despite an apparently successful procedure, CT has revealed shrinkage of the sac in only 61 per cent of patients and AAA diameter has actually increased in 21 per cent. These patients may have small endoleaks undetected on CT and interpretation of 'stenting success' should be guarded until long-term results are available.

Poster 101

Modular bifurcate aortic stent grafts

A.S. Brown *On behalf of The Northern Vascular Centre and Royal Liverpool University Hospital Aortic Stenting Groups*

Background: This study aimed to assess the mid-term results of the Vanguard aortic stent grafts (ASG) for the treatment of abdominal aortic aneurysms (AAA).
Method: Over 28 months, 371 AAAs have been assessed using computed tomography (CT). Calibrating angiography was performed on 129, of which 64 were repaired using a Vanguard ASG. Patients have been followed-up clinically and with regular contrast-enhanced CT. Morbidity and mortality were assessed with particular reference to limb patency and peri-graft flow (endoleak).
Results: All deployments were successful. Exclusion of the aneurysm sac was achieved in 55 patients (86 per cent). There were three deaths (perioperative mortality 4·7 per cent) but no major complications. Of four proximal endoleaks; one sealed spontaneously, one persists and two patients died following attempted open repair. Another patient died from a myocardial infarction on day 3. Of five distal endoleaks, three sealed spontaneously and two required further endovascular intervention. Six grafts have suffered unilateral limb occlusion and CT has identified three late distal endoleaks, each requiring endovascular repair. Three further patients have died (>30 days, two unrelated, one graft infection).
Conclusion: Mid-term results confirm that modular bifurcate ASGs are suitable for the treatment of selected AAAs. The development of late endoleaks is a cause for concern and continued follow-up is required.

Poster 102

Continuous ambulatory venous pressure monitoring in the lower limb

C. Marshall, C. Oates, K. Hose and T.A. Lees *Department of Surgery, University of Newcastle upon Tyne*

Background: Conventional study of ambulatory venous pressure (AVP) in the lower limb is a useful diagnostic tool in the management of venous disease and involves monitoring venous pressure while the patient performs standard tiptoe exercises in a laboratory setting. This method is not truly ambulatory as the equipment used is bulky and does not allow the patient to perform normal activities. A method of monitoring continuous AVP which avoids these problems has been developed.
Method: We cannulated the long saphenous vein in seven normal subjects using a blue Venflon. This was attached to a pressure transducer and venous pressure recorded using a Psion II Organiser and appropriate software. The activity of the subjects was assessed using the Numact activity monitor. This consists of two position sensors and an accelerometer connected to a Psion Series 2 Organiser.
Results: The monitoring devices were well tolerated by all subjects who were able to perform their normal activities unrestricted. A total of 47 h of monitoring were carried out. The mean venous pressure was 66 mmHg (range 47–82 mmHg).
Conclusion: This new technique is able to monitor true AVP in subjects during normal activity. This technique should prove valuable as both a research tool and clinical investigation.

Poster 103

Carotid sinus nerve blockade is of no value in carotid endarterectomy

S.J. Fearn, H.J. Chant, A.J. Picton, A.J. Mortimer and C.N. McCollum *Department of Surgery, South Manchester University Hospital, Manchester*

Background: Intraoperative local anaesthetic (LA) carotid sinus nerve blockade is believed to stabilize arterial blood pressure (BP) during carotid endarterectomy. We investigated the influence of LA and whether BP fell as LA wears off postoperatively in a double-blind controlled trial.
Method: Fifty-nine patients, mean age 69 years (range 53–84 years), were randomized to LA with 5 ml of 0·5 per cent lignocaine or placebo (normal saline) after initial dissection. Patients who had resection of the carotid sinus nerve for bifurcation reconstruction were grouped separately. General anaesthesia was standard with BP and end-tidal carbon dioxide controlled. BP was monitored via an intra-arterial cannula during and for 6 h after surgery and expressed as (i) the mean and (ii) the variability of systolic BP as the mean of standard deviations. Periods of hypotension during the wear-off period were expressed as the percentage of patients who had a fall in systolic BP of ≥20 per cent compared to the intra-operative mean for that patient.
Results:

	Systolic pressure (mmHg)				
Group (*n*)	Pre-operative	Intra-operative	6 h post-operative	Vasoactive drug use	Hypo-tension
Local anaesthetic (21)	153	139 (16·7)	126 (13·4)	81%	57%
Placebo (25)	156	136 (16·6)	132 (13·3)	72%	56%
Resection (13)	157	141 (18·8)	156* (23·0)*	62%	62%

*$P<0{\cdot}001$ analysis of variance.

Conclusion: Excision of the carotid sinus nerve is associated with higher BP in the immediate postoperative period. Lignocaine infiltration of the carotid sinus nerve is of no value in reducing fluctuations in BP during or after carotid endarterectomy.

Poster 104

The influence of carotid disease on cognitive function following coronary artery bypass

S.J. Fearn, G. Hill-Wilson, S. O'Neill*, K. Wesnes*, T.L. Hooper and C.N. McCollum *Department of Surgery, University Hospital of South Manchester, Manchester, *Cognitive Drug Research Ltd, Reading*

Background: Neurological complications are a leading source of morbidity and mortality following coronary artery bypass grafts (CABG), frequently delaying hospital discharge. The frequency of cognitive dysfunction following CABG was investigated and related to the severity of carotid artery disease.
Method: Duplex Doppler imaging of both carotids was performed preoperatively on 62 patients to seek >70 per cent internal carotid stenoses. A history of symptoms of cerebral ischaemia was recorded. A computerized battery of cognitive function (CF) tests, produced and validated by Cognitive Drug Research Ltd UK, in which patients responded to visual stimuli by pressing a yes/no button in a room free from distractions, were evaluated in terms of reaction time and accuracy. Anaesthesia was standardized with full-flow non-pulsatile cardiopulmonary bypass and 32°C hypothermia. Cognitive function was re-tested at 1 week.
Results: The table shows deterioration in mean CF at 1 week.

	Cerebral symptoms		Right carotid stenosis		Left carotid stenosis	
	Yes (9)	No (53)	>70% (7)	<70% (55)	>70% (4)	<70% (58)
Overall accuracy	0·7	0·2*	0·6	0·3	1·2	0·2**
Overall memory RT	915	147*	1254	151*	2417	109**
Overall RT	1064	267*	1346	280*	2727	220**

Results are all means, *$<0{\cdot}05$, **$P<0{\cdot}0001$, Student's *t*-test, RT = reaction time.

Patients with preoperative symptoms of cerebral ischaemia and/or carotid stenosis >70 per cent, particularly when the dominant hemisphere was involved, were slower and less accurate following CABG.

Conclusion: Although the association between carotid disease and stroke following CABG is well known, the effect on cognitive function is less well documented. Carotid disease clearly relates to cognitive dysfunction following CABG.

Poster 105

First year results of a community based leg ulcer service

R. McCarthy and H. Gajraj *Departments of Surgery and Clinical Audit, East Somerset NHS Trust*

Background: Previous reports of the high success rate of compression bandaging of venous leg ulceration have come mainly from hospital-based specialized clinics. More widespread application of the technique has been disappointing in many centres. The aim of this study was to determine whether a completely community-based leg ulcer service could achieve results comparable to a hospital-based service.
Method: All newly referred patients with leg ulceration over 12 months (01.10.95–30.09.96) were studied prospectively. Each patient in the community-based ulcer clinic was assessed by a specialist vascular nurse with continuous wave Doppler and a proforma detailing aspects of the history and the examination. Sixty-nine patients were referred directly by the general practitioner, of which 54 were suitable for leg compression. A total of 54 patients with 63 ulcerated legs were therefore analysed. All patients assessed had an active leg ulcer for more than 3 months.
Results: Forty-nine limbs were healed within 12 weeks (78 per cent) and 59 limbs were healed within 16 weeks (93 per cent). Four limbs failed to heal during the study (7 per cent). At the end of the study, recurrent ulceration was witnessed in four limbs (7 per cent). The total failure rate at 1 year was eight (13 per cent).
Conclusion: With relevant training, appropriate patient selection and the correct use of four-layer bandaging, high levels of leg ulcer healing can be achieved in an entirely community-based ulcer service without the input of a vascular surgeon.

Poster 106

What were you doing when your graft blocked?

F.C.T. Smith, L. Penny, B.M.F. Ridler, W.B. Campbell and J.F. Thompson *Exeter Vascular Service, Royal Devon and Exeter Hospital*

Background: Circumstances surrounding arterial graft thrombosis are often unknown. A study was undertaken to determine whether late graft occlusion could be associated with specific events or activities.
Method: Patients presenting with a graft occlusion between January 1995 and October 1996 completed a questionnaire requesting details of smoking, diabetes, and mobility. Patients were asked to recall any activity/event that they felt was implicated in graft failure. Hospital notes and vascular laboratory records were consulted to determine peri- and postoperative details.
Results: Forty-eight patients (35 men; 13 women) responded. Median (range) age was 68 (46–91) years. Median time to occlusion was 6 (1–108) months. Indications for reconstruction were critical ischaemia (34); severe claudication (14). Twenty-seven of 48 (56 per cent) patients admitted to continued smoking; 3/48 (6 per cent) were diabetic. At time of occlusion 44/48 (92 per cent) were mobile. Twenty-five of 48 (52 per cent) patients correlated graft failure with an activity/event. Of these, 15/16 patients with a failed PTFE BK femoropopliteal graft equated failure with a specific situation ($P<0{\cdot}0001$, Fishers exact test). Prolonged knee flexion (kneeling (4); sitting (5); travel: car (4), rail (1), aircraft (1) was related to failure of 15/25 grafts. In four patients grafts occluded whilst asleep. Dehydration was implicated in five cases: pancreatitis (1); gastro-enteritis (1); renal dialysis (1); inadequate fluid intake (+alcohol) in hot climate (2). One aortobifemoral limb thrombosed on ceasing warfarin therapy.
Conclusion: Patients' perceptions of causes of graft thrombosis are a salutory reminder of potential problems. Warning patients of the risks of dehydration, ensuring scrupulous routing of grafts across the knee, and avoidance of prosthetics where possible, are messages that must be reinforced.

Poster 107

Variability in measurement of internal carotid stenosis by arch angiography and duplex ultrasonography

G.D. Griffiths, R. Razzaq, R. Ashleigh, A. Farrell and D. Charlesworth *University Hospital of South Manchester, Manchester*

Background: The aims were: first, to determine inter- and intra-observer variability in measuring internal carotid artery (ICA) stenosis by arch angiography, using the techniques employed by the North American (NASCET) and European (ECST) symptomatic carotid surgery trials; second, to compare arch angiography with duplex ultrasound in the measurement of ICA stenosis.
Method: Three observers graded ICA stenoses bilaterally on 50 consecutive arch angiograms performed for symptomatic carotid disease using both NASCET and ECST criteria. The same patients also had duplex assessment of their ICA stenoses.
Results: Inter-observer agreement on arch angiography was moderate to good and was closer with NASCET (kappa 0·69, 0·77, 0·66) than with ECST (kappa 0·66, 0·62, 0·58). Intra-observer agreement between NASCET and ECST was poor (95 per cent agreement limits: −24 per cent to +28 per cent, ECST minus NASCET bias +1·93 per cent, Bland-Altman) and decreased with decreasing observer experience. For the best observer this gave a 5 per cent operative misclassification rate (95 per cent C.I., 2 per cent–11 per cent). Agreement between duplex and both angiographic techniques was worse (NASCET 95 per cent agreement limits: −16 per cent to +36 per cent, duplex minus NASCET bias +10 per cent; ECST 95 per cent agreement limits: −18 per cent to +32 per cent, duplex minus ECST bias +7 per cent, Bland-Altman) with a higher operative misclassification rate (21 per cent NASCET, 19 per cent ECST).
Conclusion: Variability is significant between NASCET and ECST measurements of ICA stenoses on arch angiography, but NASCET gives the more consistent results between different observers. Agreement between duplex and arch angiography (ECST or NASCET) is poor and is of considerable clinical significance.

Poster 108

Gender differences in abdominal aortic aneurysm repair

D.J. Adam, S.M. Evans, J.A. Murie, A.McL. Jenkins, C.V. Ruckley and A.W. Bradbury *Vascular Surgery Unit, University Department of Surgery, Royal Infirmary, Edinburgh*

Background: North American data have shown that female gender adversely affects selection for, and mortality from, abdominal aortic aneurysm (AAA) repair. The aim of this study was to examine whether such differences can be demonstrated in patients managed in a UK regional vascular unit.
Method: Analysis of a prospectively gathered database of 1515 patients operated for asymptomatic (n = 492), symptomatic (n = 350) and ruptured AAA (n = 673) and 139 patients who were not operated for ruptured AAA between 1 January 1976 and 31 December 1996.
Results: The male:female ratio for patients undergoing repair of asymptomatic, symptomatic and ruptured AAA was 4·8, 4·0 and 5·7:1, respectively. There was no significant difference between women and men with regard to mortality after asymptomatic (8 of 103, 8 per cent vs 22 of 389, 6 per cent, P = 0·49, Fisher's exact test), symptomatic (9 of 87, 10 per cent vs 24 of 263, 9 per cent, P = 0·83, Fisher's exact test) and ruptured AAA repair (48 of 119, 40 per cent vs 200 of 554, 36 per cent, P = 0·8,

χ^2 test). A significantly higher proportion of women admitted with rupture were not operated (54 of 173, 31 per cent vs 85 of 639, 13 per cent, $P <$ 0·001, χ^2 test) such that the overall mortality rate for rupture was significantly higher in women than in men (102 of 173, 59 per cent vs 285 of 639, 45 per cent, $P <$ 0·001, χ^2). There was no significant difference in age between women (median 74, range 51–85, years) and men (median 71, range 43–86, years) operated for rupture, or between women (median 81, range 63–93, years) and men (median 82, range 63–93, years) with rupture who were not operated.
Conclusion: These data do not support the contention that female gender adversely affects the operative mortality associated with elective or emergency repair of intact or ruptured AAA. However, fewer female patients with rupture were operated and consequently overall survival was reduced.

Poster 109

Ruptured aortic aneurysm: the decision not to operate

D.F. Hewin and W.B. Campbell *Royal Devon and Exeter Hospital, Exeter*

Background: Some patients with a ruptured abdominal aortic aneurysm (RAAA) do not undergo surgery because their prospects of survival and quality of life are so poor. The decision not to operate is often difficult. This study examined the criteria used by vascular surgeons in deciding against operation for RAAA.
Method: A questionnaire was sent to all 404 members of the Vascular Surgical Society about the organization of services for patients with RAAA, and about factors that might influence their decision against operation (no influence; may influence; seldom operate; never operate).
Results: The response rate was 81 per cent (323 replies) of whom 97 per cent practiced some case selection. Age >80 influenced 77 per cent, and 54 per cent seldom or never operated on patients >85. Of the other criteria, the single most influential factor was severe neurological disease (75 per cent seldom or never operate), while cardiac, pulmonary and renal disease influenced 22 per cent, 28 per cent and 21 per cent, respectively to operate seldom or never (74 per cent if two or more of these). Other factors that had some influence for most surgeons were cardiac arrest (85 per cent), loss of consciousness (74 per cent), prolonged hypotension (73 per cent), and long-term nursing care (87 per cent). By contrast, factors that influenced few surgeons were haemoglobin <9 g/dl (30 per cent) and absence of a close relative (33 per cent). Possible medicolegal consequences of not operating influenced only 22 per cent. If the situation becomes hopeless during the operation then 85 per cent of surgeons terminate the procedure at that stage.
Conclusion: Case selection for RAAA surgery will remain difficult, but these data help to inform the debate.

Poster 110

Is photoplethysmography useful in predicting the improvement in venous function after surgery for chronically ulcerated limbs?

J.G. Sullivan, A.S.K. Ghauri, M.R. Whyman and K.R. Poskitt
Cheltenham General Hospital, Cheltenham

Background: This study aimed to assess the role of preoperative digital-photoplethysmography (d-PPG) in predicting postoperative venous function, and therefore potential benefit of surgery, in chronic leg ulcer patients.
Method: Patients were assessed in a one-stop vascular clinic, including ankle:brachial pressure index and colour venous duplex imaging. Patients with ulcerated limbs and superficial reflux alone were offered surgery and assessed by d-PPG. Venous refill time (VRT) was measured preoperatively, with and without below-knee tourniquet (BKT), and repeated after surgery.
Results: Twenty-four limbs underwent superficial venous surgery with pre- and postoperative measurements. Median (inter-quartile range) preoperative VRT increased from 12 s (8–18·5) to 26 s (20–31·5) with tourniquet ($P<0·01$) and to 19·5 s (13·5–22) after surgery ($P<0·01$, Wilcoxon signed rank). The percentage increase in VRT with tourniquet correlated with the percentage increase after surgery ($r = 0·528$, $P = 0·01$, Spearman's rank). Median refill times for healed ($n = 19$) and non-healed ($n = 4$) limbs by 12 weeks postoperatively were as follows:

	VRT preoperative	VRT with BKT	VRT postoperative
Healed ($n = 19$)	10·7	26	21
Non-healed ($n = 4$)	12·5	23·5	13

Conclusion: PPG predicts improvement in venous function after surgery in chronic ulcerated limbs with superficial reflux alone. This may improve patient selection for surgery and predict clinical outcome.

Poster 111

What happens to patients enrolled into an exercise programme?

J.M.T. Perkins, A. Binnie, J. Collin, L.J. Hands and P.J. Morris
Nuffield Department of Surgery, University of Oxford, The John Radcliffe Hospital, Oxford

Background: This study aimed to investigate the rate of re-referral and continuing involvement for claudicants enrolled into an exercise training programme.
Method: Records were reviewed of 108 patients with intermittent claudication enrolled into an exercise programme, and followed up at 3, 6 and 12 months.
Results: Fifty-seven (53%) patients remained in the programme and under follow-up at 1 year. Of the 51 patients falling out of the programme, only eight (7 per cent) were re-referred for further surgical evaluation; five underwent angioplasty, and three had surgery. Fifteen patients (14 per cent) were discharged from the programme, 12 (11 per cent) failed to attend for follow-up, 11 (10 per cent) withdrew due to failing health, three (3 per cent) for miscellaneous reasons, and two (2 per cent) died. Patients were more likely to be discharged or withdraw (excluding death or re-referral) if they were involved in a home exercise programme ($n = 30$) compared to an exercise class ($n = 11$; $P = 0·0001$ χ^2).
Conclusion: Eighty-four per cent of patients withdrew or were discharged from the exercise programme for reasons unrelated to the need for surgical or radiological intervention. Exercise training is an effective treatment and does not merely delay the time to invasive intervention.

Poster 112

Who benefits most from an exercise training programme?

J.M.T. Perkins, A. Binnie, L.J. Hands, J. Collin and P.J. Morris
Nuffield Department of Surgery, The John Radcliffe Hospital, Oxford

Background: This study aimed to investigate which patients gain the greatest improvement in walking performance from a supervised exercise programme.
Method: Sixty-eight patients (median age 66 years, range 33–90) enrolled into an exercise programme, and were evaluated at 3, 6 and 12 months by treadmill assessment of walking performance.
Results: Overall median maximum walking distance (MWD) improved from an initial level of 98 m to 267 m at 3 months, 357 m at 6 months and 730 m at one year ($P = 0·0001$ Kruskal–Wallis ANOVA). Patients with disease confined to the superficial femoral/popliteal segment ($n = 39$) showed a greater benefit from exercise training than those with aorto-iliac disease ($n = 29$). The respective median MWD at 3 months were 371 m vs 126 m ($P = 0·009$ Mann–Whitney, at 6 months were 618 m vs 144 m ($P = 0·009$

Mann–Whitney), and at 12 months 1000 m vs 288 m ($P = 0{\cdot}07$ Mann–Whitney). Patients walked significantly further if they attended a supervised exercise class ($n = 24$) rather than being enrolled into a home exercise programme ($n = 44$), and if they recorded an initial MWD of greater than 100 m. Twenty-eight patients, who had received previous surgery or angioplasty, still improved their MWD significantly from the initial level.

Conclusion: These data suggest that patients with disease confined to the superficial femoral/popliteal segment, who have not had previous intervention, who attend a supervised exercise class, and with an initial MWD of greater than 100 m, will gain greatest benefit from exercise training.

Poster 113

The influence of systemic factors and pre-existing venous intimal hyperplasia in the detection of 'at risk' infra-inguinal vein grafts

D.K. Beattie, M. Sian, R.M. Greenhalgh and A.H. Davies
Charing Cross and Westminster Medical School, London

Background: The relevance of elevated plasma lipoprotein (a), fibrinogen, and homocysteine levels, and the presence of pre-existing venous intimal hyperplasia (IH) to the development of vein graft stenosis (VGS) have been disputed. This study aimed to investigate the association between these plasma factors, IH and outcome, and the value of these in selecting grafts at high risk of failure.

Method: Lipoprotein (a), fibrinogen and homocysteine were measured in each patient and a vein biopsy taken. Pre-existing IH was graded semi-quantitatively (0 = no IH, I = mild, II = moderate, III = severe). Patients underwent duplex graft surveillance.

Results: Sixty-three grafts in 56 patients were recruited. Forty-seven were available for follow-up (mean 15, range 5–30 months). Patients with no pre-existing IH had significantly lower homocysteine levels than those with IH ($n = 50$, $P = 0{\cdot}007$ Mann–Whitney test), but significantly higher lipoprotein (a) levels ($n = 50$, $P = 0{\cdot}012$ Mann– Whitney test). Twenty-four of the 47 grafts developed VGS. There was no association between VGS and age, sex, diabetes, or level of reconstruction. Mean plasma fibrinogen was higher, though not significantly, in those with VGS (4·16 vs 3·18 g/l, $n = 45$, $P = 0{\cdot}09$ Mann–Whitney test). Grafts with grade II/III IH were significantly more likely to stenose than those with grade 0/I ($n = 40$, $P < 0{\cdot}025$ χ^2 test). There was a highly significant association between patients with grade II/III IH and/or raised fibrinogen and VGS ($n = 38$, $P < 0{\cdot}005$ χ^2 test).

Conclusion: Plasma homocysteine levels correlated with the presence of pre-existing IH, which itself correlated with VGS. There is a marked relationship between the presence of raised plasma fibrinogen levels and pre-existing IH with the development of VGS, and these investigations may allow early identification of grafts requiring intense surveillance.

Poster 114

Endothelial dysfunction and cold pressor vasoactivity in young cigarette smokers

F. Fennessy, C. Kelly and D. Bouchier-Hayes *Beaumont Hospital, Royal College of Surgeons in Ireland, Dublin*

Background: Cold pressor vasoactivity, which is thought to depend in part on endothelial vasodilator function and also on adrenergic stimulation, was assessed in young smokers. The effects of Taurine supplementation, which we previously found to restore endothelial function, was investigated in this group.

Method: We studied five healthy smokers with a self-reported smoking history of 2-pack years and five control non-smoking subjects. Using a 7 MHz linear array ultrasound transducer, we measured brachial artery diameter in the right arm at baseline and during and after left hand immersion in ice water for 3 min. Measurements were taken during and after the cold pressor stimulus at 1-min intervals up to 10 min post-immersion. On a separate occasion a haemodynamic evaluation as performed at baseline and 1 and 3 min post-immersion of the opposite hand in ice. Cold pressor response was then re-assessed in Taurine (1·5 g/day/5 days) treated smokers.

Results: Cold pressor-induced vasodilatation was present at 1 min in controls, in contrast to smokers in whom the cold pressor stimulus induced vasoconstriction at this time point ($P = 0{\cdot}02$). After supplementation with Taurine the cold pressor-induced vasoconstriction in smokers was reduced ($P = 0{\cdot}05$). After treatment with Taurine ($n = 3$), cold pressor-induced vasoconstriction was reduced in the smokers, but vasoactivity was not restored to that of controls.

Cold pressor effect: changes in vessel diameter.

Smokers	Non-smokers	Smokers treated with Taurine
4·04% ± 1·34% Constriction	4·22% ± 5·04% Dilatation	0·5% ± 1·9% Constriction

Conclusion: These data confirm the presence of endothelial dependent and independent abnormal vasoactivity in otherwise healthy young smokers, abnormalities which may have an adverse impact on vascular reconstruction. The failure to reverse this completely with Taurine underscores the need to stop cigarette smoking.

Poster 115

Day-case varicose vein surgery is feasible for the majority of patients and has a low recurrence rate

N.T. Corrigan, J. McKeon, M.G. O'Riordain, M. Bresnihan, M.K. O'Donohoe and T.M. Feeley *Department of Surgery, Meath and Adelaide Hospitals, Dublin*

Background: While day-case surgery has become standard practice for many general surgical procedures, patients are still admitted overnight for varicose vein surgery in the majority of centres. The feasibility and results of large-scale day-case varicose vein surgery were examined in this study.

Method: All patients presenting with varicose veins to a single surgeon from 1989 to 1997 were considered for day-case surgery. Patients were included on the basis of anaesthetic suitability, adequate social support and living within 50 km of the hospital. Preoperative duplex scanning was performed routinely. Patients were scheduled for follow-up at 4 weeks and were contacted for a telephone questionnaire in September 1997.

Results: In this interval, 900 day-case procedures have been carried out on 686 patients. The mean age was 45 years (range 17–61) and the male:female ratio was 1:4. Surgery was performed for recurrent veins in 5·4 per cent. Operative procedures performed included saphenofemoral ligation with stripping of the long saphenous vein and avulsions (81·9 per cent), sapheno-popliteal ligation with avulsions (5 per cent), combined saphenofemoral and -popliteal ligation (7·7 per cent) and avulsions alone (5·4 per cent). Overnight admission was required in 27 cases (3·5 per cent). The commonest reason for admission was postoperative nausea and vomiting ($n = 11$). There were no major complications of surgery. Attendance at follow-up clinics was 92 per cent. The principal complications included pain (3·3 per cent), haematoma (1·7 per cent) and numbness (1·3 per cent). 95·6 per cent of patients were discharged after one visit. Four hundred and forty-five patients (64 per cent) were contacted by phone. Average follow-up was at 32 months (range 13–74 months). There was a reported 9 per cent recurrence rate and these patients have been offered further follow-up. More than 90 per cent expressed general satisfaction with the day-case approach and the results of surgery.

Conclusion: Day-case varicose vein surgery is feasible on a large scale, with minimal morbidity, few overnight admissions and a low recurrence rate. It could prove a useful way to reduce the long waiting lists for varicose vein surgery which exist in many hospitals.

Poster 116

Degree of internal carotid artery stenosis and plaque morphology do not influence embolization

R.C.J. Gibbs, D.B. Barratt, R.M. Greenhalgh and A.H. Davies
Imperial College of Science, Technology & Medicine, Charing Cross Hospital

Background: This study aimed to determine whether the degree of internal carotid artery (ICA) stenosis as observed by transcranial doppler (TCD) insonation of the middle cerebral artery (MCA) and plaque morphology determined by duplex were related to the propensity of a lesion to embolize.

Method: Thirty-nine patients undergoing carotid endarterectomy underwent TCD of their MCA for 30 min 2 days before surgery and all embolic signals were recorded. The degree of ipsilateral carotid stenosis and Gray Weale (GW) plaque classification were assessed by duplex preoperatively. During intraoperative MCA velocity monitoring any embolization prior to ICA clamping was recorded.

Results: Twenty patients had a stenosis between 70 per cent and 89 per cent, and 19 of 90 per cent and over. There was no difference in the two groups in terms of preoperative emboli ($P = 0{\cdot}12$), intraoperative preclamp emboli ($P = 0{\cdot}32$) or any emboli ($P = 0{\cdot}43$). The mean degree of stenosis for the non-embolic group was 87·3 per cent and for the embolic group 88·3 per cent. There was also no difference in the fall in MCA blood velocity on clamping between patients with emboli, and those without ($P = 0{\cdot}51$). There was no difference between the embolic and non-embolic group in terms of the GW classification of the plaque ($P = 0{\cdot}81$).

Conclusion: The degree of stenosis of the ICA and plaque morphology did not influence observed embolization.

Venous insufficiency and perforating veins

Perforating veins perform a normal function in transporting superficial venous blood inward to the deep system for further transit to the heart. However, in the presence of superficial reflux, normally functioning perforating veins can produce a deleterious effect on the deep venous system, causing elongation and dilatation of major deep veins and subsequent valvular insufficiency. This impairs venous function. Perforating veins may also demonstrate abnormal outward flow which may well be associated with the cutaneous changes of severe chronic venous insufficiency. In this way, perforating veins are deleterious to the health of medial ankle skin.

Deep vein reflux accompanies saphenous vein reflux in 20 per cent of limbs with varicose veins and in the apparently normal contralateral limb in 3·5 per cent[1]. This retrograde circuit was described by Trendelenburg. The usual starting point for reflux is the saphenofemoral junction but actually the reflux may develop from any proximal incompetent perforating vein such as the mid-thigh Hunterian or the anteromedial Boyd. The endpoint of this reflux is where the majority of the reflux flow re-enters the deep circulation. Treatment of this form of reflux consists of removing the superficial limb of the reflux circuit. This results in haemodynamic improvement as assessed by duplex ultrasonography[2]. In 29 limbs that demonstrated preoperative superficial femoral deep venous reflux in association with superficial reflux in the greater saphenous system, 27 were found to have total abolition of the deep venous reflux after groin-to-knee saphenous stripping. This initial report was confirmed later by Sales *et al.*[3] who described 17 limbs with reflux in the femoral deep venous system in addition to superficial reflux. All of these patients had removal of the proximal greater saphenous vein in concert with multiple stab avulsions of identified varicosities. Postoperative investigation revealed that 16 of the 17 limbs had complete resolution of the femoral reflux.

In a study of the mechanisms by which haemodynamic function improves following long saphenous surgery, Hammarsten's group[4] preserved the greater saphenous vein by flush ligation and division of the greater saphenous vein at the saphenofemoral junction, followed by interruption of the perforating veins which were detected by preoperative phlebography. These were ligated flush at the deep fascia through 2–3-cm incisions. Frequently, the skin incision was extended and the perforating vein ligated subfascially. The preoperative diameter of the long saphenous vein was reduced by 40 per cent at four different levels in the operated legs. The photoplethysmographic venous return time increased by 2·4 times above baseline and the decrease of the greater saphenous vein diameter correlated with the increase in venous refill time. So eliminating gravitational reflux by proximal saphenous vein ligation and decreasing the retrograde flow through normally functioning perforating veins by ablation of these perforating veins improved venous function and allowed the saphenous vein to decrease in diameter.

Hach[5] studied limbs by phlebography and determined that at the femoropopliteal junction the normal deep venous diameter in 75 limbs was 12 mm. However, in limbs with superficial reflux from groin to ankle, the diameter of the femoropopliteal junction increased to 17 mm. Furthermore, elongation of the vein was seen. The normal angle of the femoropopliteal junction was 158°, nearly straight; this changed to 142°, a significant angulation. An enormous popliteal vein tortuosity was also clearly seen on phlebography. Hach postulated that the calf muscle pump became overloaded because of the reflux through the greater saphenous vein re-entering perforating veins.

As some surgeons relate outward flow in perforating veins to severe skin changes of venous insufficiency, interruption of calf perforating veins by endoscopic techniques has been an attractive concept. The technique was explored early on in German-language countries where it has even been applied in the interruption of perforating veins during treatment of primary varicose veins. In that situation, it is not clear whether perforating vein interruption contributes much to the operation. In fact, the benefit of sectioning perforating veins even in limbs with chronic venous insufficiency remains unproven by controlled data. This is true even though the beneficial effects of perforator interruption are quite obvious clinically. The deleterious nature of calf perforating vein outward flow has been confirmed by endoscopic halting of outflow by subfascial perforator vein interruption. DePalma and Kowallek[6] showed in a crossover study that failure of conservative care could be reversed by intervention with sectioning of perforating veins.

Preliminary investigations by the author and his colleagues have proved the safety and efficacy of endoscopic perforator interruption and have now been extended. The single-port open-scope approach is still used. In studying patients with various grades of venous insufficiency, it was found that larger perforators are associated with more severe venous insufficiency and these are greater in number than in patients with simple varicose veins[7]. It was observed that wound healing in patients with an open ulcer is accelerated by the operative intervention[8]. The preliminary report by Gloviczki *et al.*[9] on the subject described 11 limbs in nine patients operated on by the multiple-port system and gas insufflation. In seven limbs there was improvement of ulcer healing. In three limbs the ulcer failed to heal, and in one limb the ulceration was not improved by the intervention.

In the subfascial endoscopic perforator surgery report from the North American Registry, there were preliminary data on 148 patients who had the operation in 17 institutions in 3 years after 1993[10]. Seventy per cent of the patients treated had active ulcers and 15 per cent had healed venous ulcers. The clinical score, which was a measure of morbidity due to the venous insufficiency, improved markedly from the preoperative state. During a very short mean follow-up of only 5·4 months, the venous ulcers had healed in 88 per cent of those with an active ulcer at the time of the operation.

Although it is acknowledged that normal perforating vein function assists in returning lower extremity blood to the central circulation and the heart, it appears that in pathological states the perforators are doubly deleterious. When superficial reflux is present, their normal function serves to overload and stretch the deep veins. When their check valve function fails, they are frequently associated with the severe cutaneous changes of severe chronic venous insufficiency.

Surgical treatment of anal incontinence

Anal continence is the ability both to retain faeces and to expel faeces at a proper place and at a proper time. Continence is not simply a retention mechanism, it is also the ability to defaecate in a normal way. Of the various factors that contribute to continence, the anal sphincter and pelvic floor are but two[1]. While the various surgical treatments for incontinence focus mainly on sphincter function, when it is the consistency of faeces, hyperperistalsis of the bowel, lack of compliance of the rectum or lack of sensation that are the main causes of incontinence, any operation aimed simply at restoring sphincter function will be unlikely to result in improvement. It is clear that a good clinical history and physical examination, with anorectal laboratory assessment, are essential to determine the extent to which dysfunction of the sphincter and pelvic floor contribute to the problem.

In the past most surgeons considered only the first part of the definition of continence and tried to fashion a closing mechanism. This led to the creation of a rigid narrowing of the anal canal. Examples of such surgery are the Thiersch wire and fascia lata plasty. These rigid constructions introduced an obstruction and patients were left with enormous difficulty with defaecation. Although they did not lose stool, the almost unsolvable problem of severe constipation was hardly an improvement in quality of life. Apart from the complication of obstruction, erosion of the wire or tendinous tissue through the anal canal was a frequent occurrence. Infection and pain often led to the need for a colostomy. Although in some older publications reasonable results were described in terms of restoration of continence, it is not clear whether this meant no loss of stool or restoration of controlled defaecation. None of these publications mention anything about outlet obstruction.

A more logical approach is to restore continuity to damaged sphincters[2]. The direct end-to-end suturing or the overlapping Parks anal repair gives the patient an intact circular sphincter that can close and dilate, provided that the neurogenic pathways are intact. The overall results of such an approach are quite good and much more satisfactory than those of the rigid reconstructions. Most patients develop a restoration of the anorectal inhibitory reflex, indicating an intact neurogenic input.

The pelvic floor is also considered an essential factor in anal continence. Many elderly women with incontinence have a weak puborectal sling; electromyography of the pelvic muscles shows signs of denervation and defaecography demonstrates a disappearance of the anorectal angle. Parks described the method of postanal repair to remedy this situation and, while it did, indeed, strengthen the posterior aspect of the anus with good results initially, the effect disappeared over time in most patients[2]. This is not surprising as the process of denervation is not hindered and eventually the restored anorectal angle widens. Preanal suturing of the puborectal sling, usually in combination with anal repair, gives better results.

When all treatments aimed at directly restoring sphincter or pelvic floor function fail or are contraindicated, one can consider trying to provide this function by using another muscle or an artificial sphincter. The gracilis and the gluteus are the most commonly used muscles. The latter has the advantage of being a more tonic muscle that already has an auxiliary role in 'emergency' situations; brain coordination makes it to some extent attractive to use part of the gluteus as a sphincter replacement. However, the operation is complex and it requires both gluteal muscles to encircle the anal canal[3]. Furthermore, active contraction is only possible through brain activity. The gracilis muscle is easier to free and it is technically easier to bring it around the anus. Its use has hardly any effect on leg function. The muscle is, however, fatiguable with a vast majority of type 2 fatiguable fibres. It is a voluntary muscle which can only be contracted when the patient really concentrates. However, stimulation of the transposed muscle with the help of an implanted electrical stimulator allows a change in the muscle composition towards infatiguable type 1 fibres and the muscle contracts automatically on the electrical pulses[4]. With the addition of electrical stimulation the initially unsuitable graciloplasty is transformed into an automatic non-fatiguable contractor of the anus. The stimulator can be switched on and off by remote control and in this way normal defaecation can be mimicked[4,5]. Stimulation of the gluteus needs higher voltages; the results are not as good as those of dynamic graciloplasty (which are very promising).

Implantation of the artificial inflatable sphincter has almost the same indication as graciloplasty, and with similar results. The initial fear of severe perianal infection appears unfounded[6,7]. An inflatable cuff is placed around the anus and is operated by squeezing a pump located in the scrotum or labia.

The use of sacral nerve stimulation is still experimental. It was developed to treat urinary incontinence but an influence on the anorectum was noted as a side-effect[8]. This new technique, like those outlined above, requires significant further evaluation before it will be possible to make a definite statement about indications. As always, the longer term results will be a major factor.

Background Cytogenetic studies have become an important part of tumour characterization. In a minority of tumours cytogenetic and/or molecular studies may be of help for diagnosis, selection of treatment protocols and predicting outcome.

Methods This article reviews the literature on solid tumour translocations and established family cancer syndromes. In addition, the potential importance of genetics in management of patients with breast, ovarian and pancreatic carcinoma is reviewed.

Results and conclusion Cytogenetic analysis of tumours may help confirm the diagnosis when conventional histology demonstrates no evidence of differentiation along a particular tissue pathway. For patients with well defined cancer syndromes, cytogenetic and molecular analysis offers the prospect of screening to reduce the risk of malignant disease. For many malignancies the underlying genetic anomalies are gradually being elucidated. Further studies designed to demonstrate the significance of these findings can only be undertaken if tumour material is collected and stored in optimal conditions for cytogenetic and/or molecular biological studies.

The past two decades have seen an exponential increase in our understanding of the human genome. Genetic studies in human neoplasms have not only shed light on the events leading to the development of tumours but have also suggested new methods for diagnosis, prevention and treatment of malignant disease.

Genetic alterations may be studied at different levels. Changes in the amount of DNA within tumour cells can be detected using flow cytometry or absorption photocytometry. Aneuploidy (chromosome number other than the normal diploid 46 chromosomes) has been associated with poor prognosis in a number of neoplasms, including colorectal cancer, melanoma, node-negative breast cancer, pancreatic carcinoma, neuroblastoma and acute lymphoblastic lymphoma[1–11]. Changes in ploidy are, however, only a gross measurement of overall loss or gain of DNA.

Classical cytogenetic techniques require suspensions of living cells which are capable of mitosis. If colchicine is added, cell division is arrested in metaphase when the chromosomes have replicated and separated. Metaphase spreads are obtained by lysing the cells and staining gives a unique pattern of labelling for each chromosome. This technique demonstrates the number of chromosomes present within a cell and allows detection of translocations. Fluorescence *in situ* hybridization (FISH) makes use of fluorescence-labelled DNA probes which bind in a highly specific fashion to complementary DNA sequences, allowing demonstration of structural chromosomal abnormalities in non-dividing cells.

Identification of the products of translocations or specific gene mutations requires molecular techniques. The polymerase chain reaction (PCR) allows amplification of specific regions of DNA provided that the target gene is known[12]. This technique allows identification of single nucleotide mutations. Reverse transcriptase–PCR (RT–PCR) allows amplification of messenger RNA, enabling detection of the fusion products of chromosomal translocations or tumour-specific proteins.

Chromosomal analysis of human cancer cells has demonstrated a large number of chromosomal abnormalities clustered within specific areas of the genome[13]. Although many of the tumours with consistent identifiable cytogenetic abnormalities are uncommon, they are likely to present primarily to non-specialist centres (*Tables 1* and *2*)[14–16]. The general surgeon should be aware of recent advances in tumour biology, as this has implications for the handling of surgical specimens and further management of the patient. Traditional fixation of surgical specimens in formalin followed by paraffin embedding affords excellent preservation of tissue allowing, in most instances, a clear histological diagnosis to be made following light microscopy. However, many techniques of genetic analysis cannot normally be performed on formalin-fixed tissue.

Cytogenetics and tumour classification: lymphoma subtypes

Non-Hodgkin's lymphoma (NHL) in adults has been subject to a number of different pathological classifications[17,18]. The importance of cytogenetics in differentiating the various forms of lymphoma has been documented over the past two decades. In addition, cytogenetic analysis has made an important contribution to our understanding of the pathogenesis of malignant lymphoma, and has led to the discovery of many important genes involved in cell cycle control and apoptosis.

Many of the cytogenetic abnormalities observed in NHL involve the genes encoding antigen receptors of B and T lymphocytes. These undergo rearrangement during

Paper accepted 12 January 1998

lymphocyte differentiation. Many of the cytogenetic abnormalities observed are translocations involving the immunoglobulin (Ig) heavy-chain region (IgH at 14q32) and, less commonly, the kappa and lambda light-chain gene locus (at 2p12 and 22q11 respectively) in B-cell NHL; the T-cell receptor gene loci (alpha at 14q11, beta at 7q35, gamma at 7p11 and delta at 14q11) are involved in T-cell NHL[19–22].

The translocation partners of the antigen receptor genes often involve genes that have fundamental roles in cellular physiology. For example, the t(8;14)(q24;q32) seen in Burkitt's lymphoma translocates the c-*myc* gene, which is important in the control of cellular proliferation, into the IgH gene locus and leads to c-*myc* overexpression. Abnormalities of the c-*myc* gene locus are almost universal in Burkitt's lymphoma, whether involving the classical t(8;14)(q24;q32) (seen in 80 per cent of Burkitt's lymphomas) or the kappa and lambda light-chain gene loci, and are thus important in the definition of the disease[23]. Other important genes involved in translocations with immunoglobulin gene loci include *bcl-2* at 18q21 in follicular lymphoma[24–26], cyclin D at 11q13 in mantle cell lymphoma[27–31] and 3q27 (which encodes a zinc finger protein termed bcl-6) in *de novo* diffuse large B-cell lymphoma[32–35].

In some subtypes of NHL chromosomal translocations occur which do not involve antigen receptor genes but other constitutionally expressed genes, such as the nucleophosphomin gene in the t(2;5)(p23;q35) seen in anaplastic large cell lymphoma of T/Null lineage. This

*Also known as malignant melanoma of soft parts. Identification of this cytogenetic abnormality will help differentiate these tumours from metastatic melanoma. t, translocation; d, deletion

leads to the overexpression of a novel tyrosine kinase termed anaplastic lymphoma kinase (ALK) located at 2p23[36–38] and is associated with good prognosis.

A wide variety of other numerical and structural abnormalities are observed in NHL whose exact biological significance remains to be determined. Nevertheless, it is clear that NHLs with markedly abnormal karyotypes are associated with inferior survival[39].

Cytogenetics and diagnosis: small round blue cell tumours

Small round blue cell tumours may present to almost any surgical specialty because primary sites include the orbit, facial sinuses, head and neck, chest, abdomen, pelvis, testis and limbs. This group of tumours includes the peripheral primitive neuroectodermal (pPNET) family, neuroblastoma, rhabdomyosarcoma and lymphoblastic lymphoma[40]. Although light microscopy combined with immunohistochemistry allows a specific diagnosis in the majority of cases, tumours with little evidence of differentiation continue to cause diagnostic dilemmas. Identification of tumour-specific chromosomal translocations may potentially help in differentiation of pPNET family and alveolar rhabdomyosarcomas.

The pPNET family of tumours includes tumours previously identified as Askin tumours and Ewing's sarcoma[41]. These tumours all express translocations involving the *EWS* gene located at chromosome 22q12 (*Table 2*). Three translocations known as EWS-FLI-1[42,43], EWS-ERG and EWS-ETV1[44–46] affect more than 95 per cent of all tumours classified as pPNET. If the presence of specific cytogenetic translocations is to be the *sine qua non* of this tumour group, effective diagnostic strategies must be available for their detection. This requires the availability of fresh tumour tissue for tumour cell karyotyping. Diagnostic procedures, such as FISH using fresh tumour imprints[47] and RT–PCR[44,48] using RNA extracted from fresh-frozen tumour material, may provide alternative methods of diagnosing these tumours. These techniques are currently restricted to specialist centres. However, availability of stored tumour samples frozen at −70°C may be particularly useful when diagnostic difficulties occur.

Like the pPNET family of tumours, desmoplastic small round cell tumours have a characteristic translocation. In these tumours the Wilms' tumour gene 1 at chromosome 11p13 is fused with the *EWS* gene at chromosome 22q12[49]. These tumours are classically diagnosed on the basis of microscopic appearance combined with immunohistochemical evidence of epithelial, neural and muscle differentiation[50]. Fresh tissue may be helpful in diagnosing this difficult tumour, either by classical cytogenetic or RT–PCR analysis. Availability of stored fresh-frozen tissue is essential for establishing the frequency of this translocation in desmoplastic round cell tumours. If such studies demonstrate a consistent abnormality involving the *EWS* gene, it may improve our understanding of the biology of this tumour and suggests that chemotherapy regimens similar to those used for the pPNET family of tumours could, perhaps, be more effective than other soft tissue sarcoma protocols.

Cytogenetics and prognosis: rhabdomyosarcoma and neuroblastoma

Rhabdomyosarcomas are soft tissue sarcomas which exhibit variable evidence of skeletal muscle differentiation. Although well differentiated tumours with obvious rhabdomyoblasts containing visible cross-striations like those of mature skeletal muscle are relatively easy to diagnose, undifferentiated tumours are difficult to classify using conventional histological techniques. Histologically, rhabdomyosarcomas may be broadly divided into two subtypes, alveolar and embryonal[51]. Tumours of alveolar subtype carry a worse prognosis than embryonal tumours[51,52]. However, differentiation of alveolar from embryonal tumours may be difficult because many tumours have only focal areas with classical alveolar cells. In addition, a solid alveolar variant which previously may have been diagnosed as embryonal has been identified recently[53].

Cytogenetic analysis of rhabdomyosarcomas has revealed several characteristic changes which may help the clinician make a diagnosis. This is particularly important because, in an attempt to improve long-term survival, patients with alveolar tumours receive more intensive chemotherapy than those with an equivalent stage embryonal tumour. Cytogenetic analysis of alveolar rhabdomyosarcomas has revealed that nearly all tumours have one of two characteristic translocations, t(2;13)(q35;q14) or t(1;13)(p36;q14), which produce transcriptionally active fusion proteins known respectively as PAX3-FKHR and PAX7-FKHR[54,55]. These translocations may also be detected using FISH[56] or RT–PCR[57] technology. Although a specific gene abnormality associated with embryonal rhabdomyosarcomas has not been identified, approximately 90 per cent of tumours have loss of heterozygosity of chromosome 11p15, identification of which would support the diagnosis of embryonal subtype[58].

Histological appearance and measurement of urinary catecholamines are usually diagnostic of neuroblastoma. However, the disease exhibits marked differences in aggressiveness, mirrored by heterogeneous biological characteristics[59]. Tumours which are hyperdiploid appear to carry a better overall prognosis[60], while deletion of chromosome 1p36·2–3 and amplification of the *MYCN* gene are associated with poor prognosis[61,62]. These abnormalities can be detected using cytogenetic, FISH and RT–PCR[63–65] methods. In future, it may be possible to use less toxic chemotherapeutic regimens than are currently employed for those with favourable biological characteristics.

Genetics and screening: pancreatic carcinoma

Pancreatic adenocarcinoma is the fifth most common cause of cancer death in the USA. Typically an aggressive carcinoma, it has an overall 5-year survival rate of less than 5 per cent. However, patients with small tumours (less than 2 cm) that are completely excised and have no evidence of disease dissemination or blood vessel invasion fare better, with 5-year survival rates of 20 per cent[66–68]. An improved understanding of the molecular changes responsible for the development of pancreatic cancer may lead to novel strategies allowing diagnosis and treatment at an earlier stage in the disease process.

Pancreatic carcinoma arises as part of defined genetic syndromes, namely hereditary pancreatitis[69], ataxia telangiectasia[70], hereditary non-polyposis colorectal cancer (HNPCC or Lynch syndrome II)[71,72] and familial atypical mole-malignant melanoma (FAMMM) syndrome[73] (*Table 1*). However, patients with apparently sporadic pancreatic carcinoma are significantly more likely to have a close relative with the disease (7·8 *versus* 0·6 per cent in controls)[69,71–73].

The mechanisms by which hereditary genetic syndromes predispose to pancreatic carcinoma are gradually being elucidated. Patients with ataxia telangiectasia are thought to have a mutation in the DNA repair pathway which predisposes to accumulation of mutated DNA sequences[74]. The genetic mutations in HNPCC appear to predispose to tumour development by mutations in the human mismatch repair system[75–78]. In FAMMM, mutations of *p16* may result in loss of normal control of cell division[73,79,80].

Oncogenes were the first gene family identified in tumorigenesis. These genes are mutated forms of normal cellular proto-oncogenes which result in the gene being permanently switched on. In pancreatic carcinoma, one member of the *ras* oncogene family, K-*ras*, is mutated in up to 85 per cent of tumours[81–83]. Papillary and atypical forms have the highest frequency of mutations, whereas flat mucinous lesions have the lowest rate. The near universal occurrence of a specific gene mutation in pancreatic cancer and the high frequency of mutation in lesions regarded as precursors of pancreatic malignancy are highly suggestive that changes in the K-*ras* gene are an early event in the neoplastic process. Development of diagnostic techniques to allow reliable non-invasive detection of asymptomatic tumours currently offers the best opportunity of reducing the mortality rate from this disease. Indeed K-*ras* mutations can be detected using PCR technology in pancreatic juice[84,85], peripheral blood[85] and stool samples[86]. Clearly, before the widespread introduction of screening for asymptomatic pancreatic carcinomas is undertaken, objective evidence that this improves outcome must be available. Any benefit in terms of reduced tumour mortality rate must be balanced against operative mortality rates which average 6·4 per cent and morbidity rates which vary between 25 and 40 per cent[66–68].

Cytogenetics and cancer prevention: medullary thyroid carcinoma

There is increasing interest in the influence of genetic factors in the development of malignancies in adult life. Some people carry germline gene mutations which predispose them to development of a specific cancer or group of cancers (*Table 1*). Although only a minority of people with cancer will have a well defined cancer syndrome, in 5–10 per cent of families with cancer genetic predisposition will contribute to tumour development[87]. Family studies can add a great deal to our understanding of genetic alterations in cancer as the same genes are often involved in sporadic neoplasms.

For families with multiple endocrine neoplasia (MEN) type 2, the potential to prevent death from medullary thyroid carcinoma (MTC) by detection of premalignant changes within the thyroid has been recognized for many years[88,89]. MTC may arise sporadically or as part of three well defined clinical syndromes: MEN types 2A, 2B and familial MTC (*Table 3*)[88]. MTC develops from thyroid C cells, with development of C-cell hyperplasia preceding the appearance of MTC. The established screening programme for MTC requires yearly analysis of baseline and

Table 3 Features of syndromes associated with development of medullary thyroid carcinoma

Clinical features	MEN2A	MEN2B	Familial MTC
MTC	All at risk	All at risk	All at risk
Age at onset	Typically 15–70 years	Typically < 15 years	Late onset
Disease pattern	Variable	Aggressive	Indolent
Phaeochromocytoma (%)	50	50	—
Parathyroid hyperplasia/ adenoma (%)	10–40	—	—
Inheritance	AD, high penetrance	AD, frequently new mutation	AD

MEN, multiple endocrine neoplasia; MTC, medullary thyroid carcinoma; AD, autosomal dominant pentagastrin-stimulated levels of calcitonin in those known to be at risk[89]. Although the majority of patients with MEN2A at risk of developing MTC do so between the second and fourth decades of life, recent reports from the USA highlight disease occurrence in the first decade of life[90]. More importantly, by the time raised calcitonin levels are detectable, 80 per cent have 'benign' C-cell hyperplasia and multiple foci of microscopic carcinoma. Following thyroidectomy patients with microscopic MTC remain at risk of developing clinically detectable metastatic disease if followed for long enough[90]. Clearly, the current standard management of families with MEN2A is unsatisfactory. In addition, it is wasteful of resources as on average 50 per cent of those screened are not at risk because MEN2A is inherited in an autosomal dominant fashion[88].

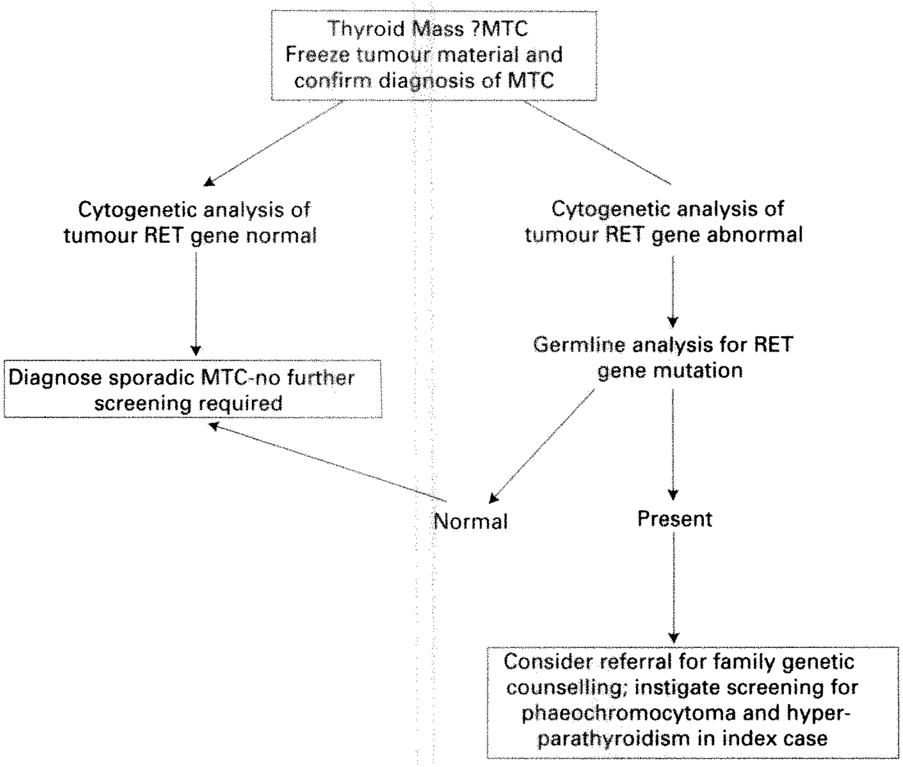
Recent advances in our understanding of the genetics of MEN2A may allow improved care for affected families as mutations of the *RET* gene located on chromosome 10q11 have been reported in this syndrome. These mutations can be identified in peripheral blood samples using currently available technology[88,90,91]. It is estimated that patients who have an abnormal *RET* gene have a greater than 70 per cent chance of developing MTC during the first four decades of life. Genetic analysis may be performed on cord blood, allowing early prophylactic thyroidectomy. However, genetic screening should only be carried out following appropriate family counselling because of the potential risks of increasing anxiety. In addition, families offered prophylactic thyroidectomy should be aware that it is far too early to be certain if early thyroidectomy will fulfil the role of screening in preventing development of incurable metastatic disease. The potential adverse affects of genetic screening will, however, be offset by reduced familial anxiety as 50 per cent of those currently being screened for development of MTC, hyperparathyroidism and phaeochromocytoma will be found not to be at risk.

Approximately 20 per cent of apparently isolated cases of MTC act as index cases for previously unrecognized MEN kindreds[92]. For patients presenting with thyroid nodules, where MTC remains part of the differential diagnosis, snap freezing fresh tumour at the time of excision may allow retrospective analysis of the *RET* gene if the diagnosis of MTC is confirmed. A simple algorithm for suggested management of patients who may have MTC is shown in *Fig. 1*.

The genetic abnormalities for MEN2B and familial MTC also reside within the *RET* gene although they involve different mutations[88]. For families with MEN2B, in which the clinical behaviour of MTC is more aggressive and known to occur as early as the first year of life[93], management should follow that for MEN2A, although prophylactic thyroidectomy may be considered at a younger age. For familial MTC, the late onset and indolent nature of the condition may mean that genetic screening is unjustified. However, if required, the algorithm for MEN2A can be easily applied to this group of tumours.

Cytogenetics and cancer prevention: breast and ovarian cancer

Increasing public awareness of the possibility that breast and ovarian cancer may be inherited has been highlighted by the news media; as a result, patients and relatives will undoubtedly approach surgeons to find out more about individual risks. Clinicians involved in the care of such patients should be aware of the advances in our



Thyroid Mass ?MTC
Freeze tumour material and confirm diagnosis of MTC
Cytogenetic analysis of tumour RET gene normal
Cytogenetic analysis of tumour RET gene abnormal
Diagnose sporadic MTC-no further screening required
Germline analysis for RET gene mutation
Normal

Consider referral for family genetic counselling; instigate screening for phaeochromocytoma and hyperparathyroidism in index case

Fig. 1 Suggested algorithm for managing patients where medullary thyroid carcinoma (MTC) forms part of the differential diagnosis

understanding of tumour biology and risk of inheritance. While knowledge of the literature may provide the former, the latter requires the surgeon to have an active role in ensuring that relevant data for a given tumour are available for accurate genetic counselling. A careful clinical history, the age of onset and tumour type in first-, second- and third-degree relatives will help identify those who potentially have an inherited cancer risk.

Mutations of the *BRCA-1* gene located on chromosome 17q2 can be identified in around 60 per cent of ovarian and 40 per cent of familial breast cancers, although only 1–2 per cent of sporadic breast cancers and 3 per cent of patients with ovarian cancer have a germline mutation[16,94,95]. It has been estimated that between 1 in 300 and 1 in 800 are carriers of *BRCA-1* mutations, with heterozygotes having an 85 and 63 per cent lifetime risk of developing breast and ovarian cancer respectively[96]. In addition, the presence of *BRCA-1* gene anomalies carries a fourfold risk of developing colonic and a threefold risk of developing prostatic carcinoma. Mutation of a second breast cancer gene, *BRCA-2*, seems to carry a similar risk to *BRCA-1*[94,97] and appears to be involved in the development of male breast cancer[98].

Although it is possible to perform germline analysis *de novo* for all patients with breast or ovarian carcinoma, this would place a considerable workload on genetic testing departments for relatively little gain. Knowledge of tumour genetic abnormalities allows a significant reduction in the number of patients requiring germline analysis, although it undoubtedly still represents a significant workload and may have to be restricted to those who are identified as being at risk on the basis of family history. However, in the long term, availability of a large number of frozen tumour samples for retrospective genetic analysis may allow more specific assessment of risk for those who come forward for prophylactic mastectomy or oophorectomy where family members have died from these diseases.

Cytogenetics and cancer prevention: gastrointestinal malignancy

Tumours of the gastrointestinal system are among the most common tumours in man; although environmental influences have been clearly implicated, it has become increasingly apparent that there are also inherited risk factors. Familial adenomatous polyposis coli (FAPC)[99–101], ataxia telangiectasia[68,72] and HNPCC[73–76] predispose to development of adenocarcinoma of the stomach. In a small number of families an autosomal dominant pattern of inheritance has been reported. The majority of gastric tumours are apparently sporadic. However, there is an excess risk of first-degree relatives developing gastric carcinoma when the proband is less than 50 years old at the time of diagnosis, suggesting that an inherited risk factor may exist in these families[102]. Although structural and numerical abnormalities of a number of chromosomes have been identified in gastric tumours, a germline mutation which would allow development of screening tests has yet to be recognized[103].

Malignant tumours of the duodenum and small bowel are rare in comparison to malignancy of the colon. FAPC predisposes to the development of periampullary and small bowel carcinomas[99,100], Gorlin's basal cell nevus syndrome to carcinoid tumours[104] and neurofibromatosis[105] to neurofibromas and neurofibrosarcomas. Endoscopic surveillance of those known to carry the mutations characteristic of these conditions may be of value in detecting asymptomatic (early stage) disease.

The general population has a 6 per cent lifetime risk of developing colon cancer. The vast majority of these tumours are sporadic, with hereditary polyposis syndromes accounting for approximately 1 per cent and HNPCC for 5–10 per cent[99,100]. Currently all members of families known to have FAPC are screened for the appearance of polyps during the second to fifth decades of life, although the autosomal dominant pattern of inheritance means that only 50 per cent are at risk of developing the disease. FAPC is associated with abnormalities of the adenomatous polyposis coli gene (*APC*) located at chromosome 5q21[101], offering the possibility of germline screening for members of kindreds with familial polyposis coli. Gardner's syndrome and possibly Turcot's syndrome are other hereditary polyposis syndromes associated with abnormalities of the *APC* gene[99] for which genetic screening may also be possible.

HNPCC accounts for the majority of inherited colonic carcinomas. The genetics of this hereditary syndrome are gradually being elucidated, with four candidate genes identified[73–76] (*Table 1*). Those known to be at risk of developing colonic carcinoma require regular screening by endoscopy. Again, an autosomal dominant mode of transmission means that only 50 per cent of those screened are actually at risk of developing the disease. Identification of specific gene abnormalities may allow targeting of screening programmes to those known to carry the mutated gene, and may in the future allow prophylactic colectomy at an earlier stage in the disease process.

Conclusion

Over the past decade there have been considerable advances in tumour molecular and cytogenetic analysis which may help in the diagnosis, treatment and prevention of cancer. Cytogenetic analysis of tumour material has identified specific translocations in many rare sarcomas (*Table 2*). The identification of diagnostic chromosome translocations in histologically undifferentiated tumours may support a diagnosis which is doubtful on histological grounds alone, or may lead to a reconsideration of the histological diagnosis. In addition, cloning of the breakpoints involved in lymphoma- and sarcoma-associated translocations opens up new opportunities for molecular diagnosis and detection of minimal residual disease. Tumour cytogenetics is likely to play an increasingly important part in directing cancer therapy. However, most techniques currently available for cytogenetic analysis are only suitable for use on fresh tumour material. Surgeons should consider the implications of routinely placing tumour samples in formalin before sending them to the pathology department.

The United Kingdom Children's Cancer Study Group (UKCCSG) has recommended for many years that any tumour arising in childhood that is biopsied or excised should be submitted for cytogenetic analysis, cryopreservation and routine histological analysis. To ensure that UKCCSG recommendations are carried out, all surgeons operating on children with potential tumours should make appropriate arrangements with their pathology department before tumours are excised.

For adult patients the situation is much less clear. For families with a known cancer predisposing syndrome

(*Table 1*) tumour material should ideally be submitted for cytogenetic analysis and cryopreservation. When a tumour is likely to be a sarcoma, cytogenetic analysis may prove invaluable in making a diagnosis (*Table 2*) and submission of fresh tumour tissue should be considered.

Surgical specimens require to be divided so that portions can be submitted for cytogenetics and cryopreservation, as well as for routine histological analysis. As correct handling of tumour samples is essential for cryopreservation which will allow analysis by RT-PCR, and for cytogenetic analysis by karyotyping or FISH on tumour imprints, the pathologist requires advanced warning. In the operating theatre, tumour samples should not be placed in formalin. Instead they should be sent dry or wrapped in foil (not filter paper which induces dehydration artefacts) for the immediate attention of the pathologist. Undue delay in cryopreservation must be avoided at all costs, as RNA used for RT-PCR analysis is rapidly degraded in samples left at room temperature. Where facilities for handling specimens for long-term cryopreservation and cytogenetic analysis are not available, patients should be referred to a centre where such facilities exist. Routine submission of fresh tumour material from most patients with carcinoma at the present time would impose impossible pressures on pathology and genetic resources. The benefit would, in any event, be uncertain as at present most genetic events associated with tumour development appear not to be inherited.

As our knowledge of tumour biology increases, more sophisticated cytogenetic and molecular analysis of human tumours will be needed; provision of facilities outside specialist institutes will have to be considered.

Review

Port-site metastases following laparoscopic surgery

S. J. NEUHAUS, M. TEXLER*, P. J. HEWETT* and D. I. WATSON

Background Application of laparoscopy to the resection of malignancy has been followed by a literature describing cases of metastatic involvement at laparoscopic port sites. These include patients who underwent surgery for early stage carcinoma and instances following laparoscopic procedures during which tumours were not dissected.

Methods Recently published clinical and experimental studies, and case reports related to this problem are reviewed; their relevance is discussed.

Results Experimental studies incorporating bench top and large animal models have confirmed that tumour cells may be redistributed to port sites during laparoscopic surgery either directly from contaminated instruments or indirectly via the insufflation gas. Small animal models suggest that the incidence of wound metastasis is increased following conventional laparoscopic surgery, and that it may be decreased by gasless laparoscopy or helium insufflation. This evidence suggests that the development of port-site metastases depends not only on the physical redistribution of tumour cells but also on the specific insufflation gas used, possibly because of influences on local metabolic or immune factors acting at the wound site.

Conclusion Further research in this area is urgent. Until the issue is better understood, patients undergoing laparoscopic surgery for malignancy should be entered into clinical trials.

Since the first report of metastasis to a laparoscopic port site by Döbrönte *et al.*[1] in 1978, it has become increasingly clear that the laparoscopic manipulation of both abdominal and thoracic malignancies may be followed by metastasis to surgical access wounds. Whether this is more likely following laparoscopic than open surgery is controversial[2–4]. However individual case reports, as well as the results of recent experimental studies[5–9], suggest that this problem is significant.

A critical review of the issue is warranted, as laparoscopic techniques, while attractive in terms of cosmesis, shorter hospital stay and reduced postoperative pain[10], cannot be justified if they result in an incidence of recurrent malignant disease in surgical access wounds which compromises long-term outcome. Wound seeding of a potentially curable malignancy is a disaster which may change a curable condition into an incurable one. Furthermore, recurrence after palliative laparoscopic resection may compromise quality of life. Consequently, many surgeons have expressed concern about the appropriateness of the application of laparoscopic techniques to the surgical treatment of malignancy[2,3,9,11].

Paper accepted 12 January 1998

Evidence from clinical cases

Since 1978, in excess of 100 reports of metastasis to laparoscopy wounds have appeared in the surgical and gynaecological literature[12]. These include instances of metastasis following diagnostic laparoscopy or laparoscopic resection of carcinoma of the gallbladder[3,13,14], ovary[1,15,16], pancreas[4,17], colon[18–20], bladder[21,22], stomach[23] and liver[24]. Of concern are reported instances of metastasis following laparoscopy when it has been documented that the primary tumour was not manipulated during the procedure[17,25] as well as metastasis following laparoscopic colectomy for Dukes A colonic lesions[20,26], mucosal gallbladder cancer[6] and carcinoma *in situ*[3] (*Tables 1* and *2*). It is also important to realize that this problem is not exclusive to laparoscopy; it has also been associated with thoracoscopic cancer resection[29,31,32].

Following the early case reports, Nduka *et al.*[2] published the first review of the problem in this Journal in 1994, describing a collected series of 20 cases, all adenocarcinomas. Wibbenmeyer *et al.*[3] in 1995 reviewed a population undergoing laparoscopic cholecystectomy and reported a 1 per cent incidence of gallbladder cancer in the patient group studied. Laparoscopic cholecystectomy was associated with an increased risk of dissemination and

Table 1 Case reports of port-site metastases developing following laparoscopic surgery without tumour manipulation

Reference	Year	Procedure	Tumour type

Nduka *et al.*[2]	1994	Gallbladder carcinoma	'Non-invasive'
Perracchia *et al.*[30]	1993	Oesophageal carcinoma	$T_2 N_0 M_0$

diffuse peritoneal seeding of tumour, compared with historical experience with open cholecystectomy. A retrospective analysis of 219 patients with ovarian cancer was reported by Kruitwagen *et al.*[33] in 1996. Seven of 43 of these patients developed tumour secondaries at port sites following a preliminary diagnostic laparoscopy. Martinez *et al.*[12] also reviewed the clinical literature in 1995. Their series comprised 105 cases: diagnostic laparoscopy (five), laparoscopic cholecystectomy (42), gynaecological surgery (13), colorectal surgery (34), thoracoscopic surgery (seven) and urological surgery (four).

Implantation of tumour following open resection of thoracic tumour is rare[31,34] and usually involves surgery for mesothelioma. Wound metastases following oesophagectomy are similarly uncommon[35]. Following the advent of thoracoscopic lung resection for malignancy, however, an increasing number of implantation metastases have been reported[29,31]. In 1996 Downey *et al.*[31] described 21 cases of wound dissemination of malignant tumours following video-assisted thoracic surgery. These occurred as a result of operation for both primary and secondary lung tumours. The majority of the port-site metastases were adenocarcinomas, although squamous cell carcinoma, small cell carcinoma, medullary carcinoma of the thyroid and melanoma were also recorded. Port-site metastasis has also been reported following minimally invasive oesophagectomy[31,32].

The incidence of tumour involvement of the laparotomy wound in patients undergoing open colectomy for carcinoma is less than 1 per cent according to both Hewett and Baxter[36] and Hughes *et al.*[37]. Reilly *et al.*[38], in a prospective study of 1711 patients undergoing open colon cancer resection, found the incidence of this complication to be 1·5 per cent. By contrast, both Wexner *et al.*[39] and Prasad *et al.*[20] estimate that the incidence of wound metastasis following laparoscopic colectomy is approximately 4 per cent. However, all of these estimates are crude and, in the absence of better data to define both the actual number of port-site recurrences in the community (numerator) and the number of laparoscopic resections (denominator), the exact incidence remains unknown. Because of the limitations of data collection methodology (perhaps with the exception of that of Reilly *et al.*), it is possible that historical estimates of the incidence of wound metastasis following open surgery have been underestimated.

Clinical presentation of port-site metastases and prognostic significance

The period between laparoscopic surgery and the clinical finding of a wound metastasis varies. It may occur as early as 7 days after operation[23,40], but most lesions arise between 3 and 9 months later[2,12,33,41]. Metastases typically present as hard, painful nodules at the previous site of one or more of the laparoscopic cannulas[2,12]. Kruitwagen *et al.*[33] assessed the effect of port-site metastasis on patient survival and found that the presence of a metastasis at the site of a trocar or paracentesis access wound correlated adversely (although not statistically significantly) with survival. This analysis was performed following adjustment of data for factors such as age, tumour stage, pre-existing illness and tumour histology.

It has been proposed that the development of port-site metastases correlates with the aggressiveness of the primary tumour and/or its stage[17,33], i.e. it is a prognostic indicator which is independent of the surgical approach (*Table 3*). However, laparoscopic surgery for tumours with low metastatic potential, such as a borderline ovarian tumour[28] or Dukes A colon carcinoma[20,26], has resulted in this phenomenon, suggesting that outcome may be adversely affected (*Table 2*).

Table 3 Interpretations of port-site metastasis

The incidence of metastasis is similar to that associated with open surgery
Metastases are more common following laparoscopy, but reflect the preoperative prognosis of the tumour. They do not adversely affect outcome
Metastases occur in patients who might otherwise have expected to have been disease free following open surgery. Prognosis is adversely affected

Experimental models

A number of experimental studies which seek to improve understanding of port-site metastasis have been reported recently. The models are usually one of three types. *In vitro* studies may be used to evaluate cell movement during laparoscopy[42,43]. These models are somewhat artificial and it is difficult to extrapolate results obtained in a rigid plastic pseudoabdomen to the clinical setting. Animal models are more analogous to clinical situations. Large animals (usually pigs) have been used to test for cell movement during laparoscopy using either radiolabelling techniques or micropore filters combined with cytological examination[43–45]. While the volume of the pig abdomen closely resembles that of the human, the lack of native tumour lines precludes testing for the endpoint of tumour growth. Nevertheless, these models may be useful for studies which map the intraoperative movement of tumour cells during laparoscopy.

Small animals (mice, rats, hamsters) have also been used[46–48]. Inbred, immune competent strains with native tumour lines[9,47,49], or immune compromised strains with human cancer cells[7,45], allow the endpoint of tumour growth to be tested. While the peritoneal cavity is much smaller than that of the human, these models can be used to examine variations in the laparoscopic environment rather than the simple mechanical manipulations tested in larger animals.

Evidence from *in vitro* and large animal models confirms that tumour cells are delivered to port sites via the laparoscopic environment[42–44,49]. There is little doubt that direct spread by contaminated instruments can account for this[44,50,51]. The role of tumour cells in aerosols causing indirect transfer to port sites is more controversial. Such aerosols have been demonstrated in a pig model[52] but their occurrence alone is not adequate evidence that they are responsible for the development of tumour metastasis[53]. Studies in small animal models have demonstrated a threefold to fivefold increase in the incidence of wound metastasis following laparoscopy with carbon dioxide compared with laparotomy[9], and adverse patterns of tumour growth following carbon dioxide pneumoperitoneum[49].

Effect of laparoscopy on tumour growth

It is believed that primary tumour growth rates are influenced by the degree of operative trauma[54,55], largely through the depressant effect that the latter exerts on systemic immunity[56–61]. Laparoscopy, because it creates less access-related trauma, may cause less suppression of immune function and so be less likely to facilitate tumour growth[61,62]. Allendorf *et al.*[60,63,64] support this concept. They demonstrated in a mouse model that tumour cells inoculated into the dorsal skin grow more easily and aggressively after laparotomy than after laparoscopy with carbon dioxide insufflation. This suggests a benefit in favour of laparoscopy in the treatment of malignant conditions. However, it is important to note that this study examined only extraperitoneal tumour growth. Interestingly, when Griffith *et al.*[65] investigated the effect of surgery on immune function by examining the effect of open and laparoscopic operation on natural killer cell cytotoxicity, they found a similar degree of immune suppression in both groups.

Others have used a rat model with the introduction into the peritoneum of free cancer cells to show that, while the presence of a port may predispose to port-site metastases, the presence of a pneumoperitoneum does not in itself enhance the implantation of free cancer cells[47]. In this study, however, insufflation was for only 10 min, which limits the time that pneumoperitoneum had to exert any possible adverse effect. In contradistinction to this, Voltz *et al.*[56] have demonstrated that the induction of a carbon dioxide pneumoperitoneum results in an increased seeding rate of intraperitoneal tumour cells, and also increases both the number and size of intra-abdominal metastases. This suggests that laparoscopy might result in a worsening of prognosis compared with laparotomy. Mathew *et al.*[9] demonstrated increased growth of a lacerated 'primary' tumour following laparotomy compared with laparoscopy, but significantly fewer wound metastases. It remains to be proven that the systemic immunological benefit of the laparoscopic approach has clinical merit as it is possible that adverse local factors associated with laparoscopy lead to early tumour recurrence in wounds.

Mechanisms of metastasis

Several possible explanations for the occurrence of port-site metastases have been proposed; it is likely that the aetiology is multifactorial (*Table 4*). Most contributing factors seem specific to the laparoscopic environment, although evidence supporting current understanding of this problem has been derived exclusively from animal models (*Table 5*). Cells may implant in wounds because of direct contact with contaminated laparoscopic instruments[2,44,67]. Frequent changes of instruments may predispose to this[44,50], and extraction of the tumour through a port wound may lead to coating of the port site with viable tumour cells[2,44,50]. This may be particularly relevant when extracting a relatively large tumour through a small access wound, where traumatic manipulation of the tumour may predispose to a substantial release of cells. It has also been suggested that direct contact between the abdominal wall and tumour may occur during periods of temporary loss of pneumoperitoneum[44,45].

Table 4 Possible mechanisms which lead to port-site metastasis

Mechanical		
	Direct contamination	
		Seeding during extraction of tumour through a small wound
		Seeding by contact with instruments contaminated with tumour cells
	Indirect contamination	
		Seeding into the wound during episodes of desufflation of the pneumoperitoneum
		Cells exist in an aerosol and are transferred to wounds and ports without direct contamination (chimney effect)
Metabolic/immunological		
		Seeding occurs in both open and laparoscopic wounds, but metastases are more likely after laparoscopy because of locally acting immunological and/or metabolic factors
Haematogenous		
		Seeding by haematogenous spread during surgery

Table 5 Information obtained from experimental models

In vitro/ex vivo studies	
	Ports and instruments are easily contaminated with tumour cells during laparoscopic surgery by direct contact[43]
	Tumour cells existing in aerosols have not been demonstrated[53]
Large animal studies	
	Ports and instruments are easily contaminated with tumour cells by direct contact[44,45,50]
	Tumour cells in aerosols have been demonstrated in some studies[52]
Small animal studies	
	Laparoscopy is associated with less growth of 'primary' tumours, and less overall immune suppression[48,60]
	Carbon dioxide pneumoperitoneum results in adverse patterns of intraperitoneal tumour growth[46–49]
	The likelihood of wound metastasis is increased three to five times by carbon dioxide pneumoperitoneum[9]
	Wound metastasis is less likely following gasless laparoscopy[48,66]
	Helium laparoscopy may reduce the risk of wound metastasis[7,26]

The indirect spread of tumour cells to surgical access wounds has also been proposed as an explanation for the phenomenon. Viable tumour cells are liberated into the peritoneal cavity during the resection of malignancy by conventional techniques[67–70] and many believe that, in the presence of a pneumoperitoneum, these exfoliated cells can be carried in an aerosol to implant in the laparoscopy access wounds. Implantation of exfoliated cells has been demonstrated to occur during open surgery[37,67]. Laparoscopic techniques are inherently less dextrous than open surgery and this may predispose to an increased burden of exfoliated tumour cells.

Evidence from clinical case reports suggests that neither instrument contamination nor direct implantation of exfoliated tumour cells is likely to be the sole mechanism for this phenomenon. Port-site tumours have been reported at sites where direct contamination is improbable, and in cases in which the primary tumour was not manipulated. Watson[17] has described the development of multiple abdominal wall metastases from a pancreatic carcinoma after laparoscopic gastroenterostomy. In this instance the theory of direct implantation is not feasible as the lesser sac was not opened and the tumour was not manipulated. A similar case following laparoscopic cholecystectomy was reported by Jorgensen *et al.*[25].

Haematogenous spread of tumour from the primary lesion to the port site has also been proposed, but this is an unlikely mechanism. Murthy *et al.*[55] have demonstrated that, when tumour cells are injected intravenously, wound metastases are rare, although they do arise at sites of intra-abdominal surgical trauma. It is possible that the positive pressure environment in the peritoneal cavity during pneumoperitoneum, along with the spillage of cancer cells into the peritoneal cavity and on to raw surfaces, may lead to viable tumour emboli entering the circulation. However, if this were the case, one would expect an increased rate of tumour metastasis to the usual sites of secondary involvement as well as to access wounds.

Local factors at the sites of port placement may contribute to the localization of tumour metastases. It is known that tumour preferentially spreads to recently traumatized tissues and that malignant cells grow more easily in areas of high cellular proliferation[55]. While the intact peritoneum is resistant to tumour cell implantation[9,46], the port site provides a localized peritoneal breach and an area of high cellular proliferation associated with the healing wound. The associated local release of inflammatory regulators[54,58,71] may generate an environment which facilitates the subsequent development of tumour metastasis. This mechanism alone, however, does not provide a complete explanation for an increased incidence of port-site metastases associated with laparoscopic surgery. It is, however, possible that small wounds, such as those created by laparoscopic trocars, produce a different environment for healing than large laparotomy wounds. The immunological or inflammatory response in these two different types of wound may be dissimilar.

Pneumoperitoneum-specific factors

A major difference between an open laparotomy and a resection performed laparoscopically can be found in the provision of access space for both vision and operative manipulation. For laparoscopy this is generally achieved by the creation of a pneumoperitoneum, involving the introduction of gas under pressure into the peritoneal cavity. Factors specific to the pneumoperitoneum which may play a role in the development of port-site metastases include mechanical effects of gas under pressure, potential metabolic and immunological effects due to the insufflating gas, alterations in peritoneal humidity, stretching of the abdominal wall and peritoneal lining, possible electrostatic interactions with trocars and pressure–flow effects related to the use of insufflating gas.

Nduka *et al.*[2] have suggested that the pneumoperitoneum acts as a closed system through which airborne particulate matter must circulate, whereas during open surgery this particulate matter tends to be drawn away by the theatre ventilation system. This may result in 'trapping of viable tumour cells by moist peritoneal surfaces'[2]. A so-called 'chimney phenomenon' has also been proposed[45]. This invokes the development of a Venturi effect, whereby the insufflation of carbon dioxide causes turbulence which displaces tumour cells. These cells are concentrated from an aerosol as a result of the leakage of carbon dioxide alongside port sites. This results in tumour implantation[46,48,49,72]. Tumour cells from aerosols may adhere to ports via attractive forces (electrostatic or molecular) or be deposited on them from instruments. When a port is removed, these tumour cells may be wiped off and deposited within the port-site wound. It is also possible that carbon dioxide gas under pressure dissects between tissue layers at the port site, thereby causing additional trauma and allowing tumour cells to lodge between muscle, fascial and peritoneal surfaces.

The presence of a pneumoperitoneum also results in stretching of the abdominal wall. This may augment the release of inflammatory mediators, such as transforming growth factor alpha, which are involved in the healing of wounds and may also promote tumour proliferation[46,71,73,74]. It is possible that alterations to pressure and flow rates during laparoscopy could affect a series of complex local and systemic metabolic and immune responses which may in turn facilitate tumour survival and implantation.

Influence of specific insufflation gases

Experimental studies using small animal models have demonstrated that the incidence of wound metastasis is reduced by eliminating carbon dioxide insufflation by using gasless laparoscopy[48,66]. Watson *et al.*[66] suggest that the incidence following gasless laparoscopy is similar to that following laparotomy. These experiments imply that an effect specific to laparoscopic insufflation accounts for the increased incidence of wound metastases proposed from clinical reports. Most studies have utilized carbon dioxide as the insufflation gas with the assumption that the physical effects of carbon dioxide pneumoperitoneum account for wound metastasis. However, three recent experimental reports[7,75,76] detail the effect of different insufflation gases on tumour behaviour during laparoscopy; the data are somewhat conflicting. Jacobi *et al.*[7] report a series of *in vitro*, *in vivo* and *ex vivo* experiments using a rat model and colonic tumour line. While the insufflation of carbon dioxide resulted in greater tumour growth than that of a control group, helium had no tumour enhancing effect. Dorrance *et al.*[75], however, using a rat tumour cell line, report that the promotion of tumour growth by laparoscopy is independent of the insufflating gas; this study used an aggressive breast cell cancer line which may have minimized differences between the treatment groups. Neuhaus *et al.*[76] compared carbon dioxide, helium, nitrous oxide and compressed air as insufflation gases to facilitate the laparoscopic laceration of an implanted solid tumour in a rat model. The incidence of port-site metastases was significantly reduced in rats undergoing helium insufflation, compared with the other groups. Because helium is an inert gas which generates no adverse metabolic effects[77,78], this study suggests that the development of port-site metastases may be influenced by metabolic determinants as well as the physical redistribution of tumour cells by the laparoscopic environment.

Voltz *et al.*[56,71] have demonstrated that the pneumoperitoneum results in significant mechanical, ventilatory, cellular, hormonal and immunological changes, and that these are influenced by intra-abdominal pressure, the insufflation gas used and the duration of insufflation. The specific adverse effects identified include severe acidosis involving the peritoneal surface and the underlying connective tissue, disturbances in electrical surface charges, and the release of various mediators such as endotoxin. The severe acidosis generated by carbon dioxide pneumoperitoneum, combined with raised intra-abdominal pressure, may impair macrophage function[56,71]. The insufflation of carbon dioxide has also been shown to compromise intraperitoneal macrophage activity and depress immunological responses in CD-1 mice, compared with laparoscopy with air insufflation[73]. Supporting this, West *et al.*[79] recently noted that carbon dioxide can transiently inhibit the ability of peritoneal macrophages to secrete inflammatory cytokines, particularly lipopolysaccharide-stimulated tumour necrosis factor and interleukin 1. This effect was not noted with air or helium. Carbon dioxide is also irritant to the peritoneum and this, via the release of inflammatory mediators such as transforming growth factor alpha, may favour tumour implantation at the raw peritoneal surfaces created by laparoscopy access ports[71].

Prevention of cutaneous metastases

Although the causes of port-site metastases remain uncertain, many investigators have suggested preventive strategies. These include port-site protection[80,81], the use of prophylactic tumoricidal agents[2,12,82–84], wound 'sterilization'[85] and gasless laparoscopy[66].

Port-site protection involves the use of plastic bags or wound protectors to prevent direct contact between a resected specimen and the port site[2,80,81]. It is also sensible to avoid traumatic manipulation of tumours which may shed tumour cells into the peritoneal cavity, and to ensure that the incision through which the specimen is retrieved is wide enough to avoid further inadvertent shedding of tumour cells[12,86]. As clinical cases have been reported in which tumour recurrence has occurred at port sites other than those used to deliver the tumour, this strategy alone is unlikely to prevent all port-site tumours.

The use of tumoricidal agents to destroy viable intraperitoneal cells and so prevent their implantation was originally proposed for open surgery more than 30 years ago[87]. It has more recently been suggested as a strategy to prevent port-site metastases[2,12,82]. Tumoricidal agents may be delivered by parenteral or intraperitoneal routes[67,87–89]. The efficacy of intraperitoneal chemotherapy at the time of surgery for gastric and ovarian cancers has been demonstrated for conventional surgery[88–90]. Lavage of the peritoneal cavity with large volumes of 0·9 per cent saline has also been proposed[91] as a preventive strategy. At present no experimental or clinical evidence has been published to support the routine use of tumoricidal agents during laparoscopic surgery.

The excision of laparoscopic port sites following procedures which involve malignancy has been advocated[3,8]. The disadvantage is that it may negate a principal benefit of minimal access surgery, namely small wounds. It is also not certain that the resultant wounds would be any less likely to become involved with metastatic tumour than the original ones. The use of low-energy carbon dioxide laser light[85] has been described for the 'sterilization' of mastectomy fields to prevent wound recurrence. This has also been proposed for use in laparoscopic surgery, although supporting data are yet to be published[2].

Gasless laparoscopy, which provides laparoscopic access without positive pressure pneumoperitoneum, is feasible[66,92]. However, existing devices used to maintain a working space give rather poor access in the flanks, making colonic mobilization awkward during laparoscopic colectomy. Nevertheless, because experimental evidence suggests that avoiding pneumoperitoneum may significantly reduce port-site tumours[48,66], this strategy (along with helium insufflation) warrants further investigation.

Conclusion

Recent evidence from clinical cases and experimental studies confirms that the incidence of wound metastasis following cancer surgery is increased with the laparoscopic approach; its occurrence following treatment for early stage cancers suggests that prognosis may be adversely influenced. The problem occurs despite the apparent reduction in systemic immune suppression and primary tumour growth following laparoscopic treatment of cancer in experimental models. It is likely that the mechanism of wound metastasis is multifactorial. Laparoscopy can result in the mechanical redistribution of tumour cells directly by spread from contaminated instruments and indirectly due to the mechanical effect of the insufflation gas. Metabolic and immunological factors specific to carbon dioxide insufflation, acting locally at the port site, may also be important. While experimental studies support further clinical investigation of the roles of gasless laparoscopy and helium insufflation in laparoscopic cancer surgery, a role for tumoricidal agents remains speculative. Until the issue of laparoscopy-associated wound metastasis is fully understood, laparoscopic cancer surgery should take place only within the context of clinical trials.

Review

Upper gastrointestinal disease in patients with familial adenomatous polyposis

M. H. WALLACE and R. K. S. PHILLIPS

St Mark's Hospital, Northwick Park, Watford Road, Harrow HA1 3UJ, UK
Correspondence to: Mr R. K. S. Phillips

Background Upper gastrointestinal disease has become an important aspect in the management of patients with familial adenomatous polyposis (FAP).
Methods A review of the literature was carried out using Medline. Epidemiology, pathology and treatment options are considered.
Results and conclusion Despite the fact that over 90 per cent of patients with FAP develop duodenal adenomas, only 5 per cent go on to develop cancer. In the absence of methods to detect who is at risk of cancer, all patients undergo regular endoscopic surveillance at present. Chemoprevention in the form of drug therapy may be the answer to controlling the disease.

Despite screening and prophylactic surgery significantly improving the survival of patients with familial adenomatous polyposis (FAP)[1–3] their life expectancy remains lower than that of the general population[4]; cancer, desmoid disease and the long-term consequences of surgery are the three main reasons[1,3,5]. The upper gastrointestinal tract is the commonest site of cancer after prophylactic colectomy, probably because the duodenum is the second commonest site of polyp development after the colon[6].

Historical aspects

Gastric polyps in FAP were first described in 1895[7] and duodenal polyps in 1904[8]. The first description of a duodenal cancer was in 1935[9], gastric cancer not being reported until 1962[10]. In the 1960s interest in upper gastrointestinal polyposis grew[11], with Duncan *et al.*[12] suggesting as early as 1968 that all patients with FAP should undergo regular upper gastrointestinal surveillance to detect polyps, at that time by barium radiology[13]. This view did not catch on, even when endoscopy was introduced in the 1970s. Indeed patients were only investigated if they had symptoms, such as abdominal pain or unexplained anaemia, or if they had presumed family preponderance for upper gastrointestinal polyps. When reporting retrospectively, various centres reported that approximately 50 per cent of their patients had duodenal adenomas (*Table 1*). In 1989 two groups[23,24] reported prospective studies showing a much higher incidence, with 90 per cent or more patients with FAP having duodenal adenomas. Later studies have found somewhat less than this, but these studies have contained small numbers, or

were not prospective, or did not use side-viewing endoscopes with random biopsy.

Epidemiology

Adenomas tend to be noted in the duodenum approximately 15 years after colonic polyps occur[21,33,34], but this may simply reflect the time when they are sought. At presentation, clinicians tend (reasonably) to concentrate on the large bowel manifestations, turning only to duodenal surveillance as patient's age.

Outside FAP, duodenal cancer is rare, with an incidence of 0·01–0·04 per cent in the general population[35]. Men are more often affected, usually in the sixth decade. Polyposis is associated with a high frequency of duodenal or periampullary cancer with estimates of between 1 and 12 per cent[33,36], and men and women are equally affected. The average age at which the diagnosis of duodenal cancer is made is 50 (range 18–78) years[13,32,33,37–40], approximately 10 years after the expected development of colonic cancer in untreated FAP[41]. Life-table analysis of 222 patients who had undergone colectomy and ileorectal anastomosis showed a 3·35 relative risk of dying compared with the general population, upper gastrointestinal malignancy being the commonest cause[4]. Pauli *et al.*[42] estimated the periampullary cancer risk to be 100–200-fold greater than that of the general population, and Offerhaus and colleagues[38] put the relative risk of duodenal adenocarcinoma at 331 and ampullary carcinoma at 124.

Gastric cancer risk is not increased in Western families, but is reported to be high in Japanese and Korean families with FAP. The increase in these countries is not simply related to the high background cancer rate, as patients with FAP have an observed:expected mortality ratio for gastric adenocarcinoma of 3·43 compared with the general Japanese population[43,44].

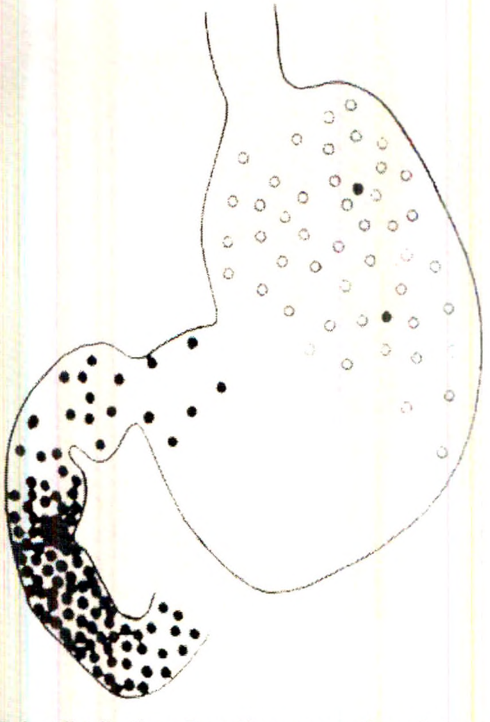

Fig. 1 Polyp distribution. Overall representation of sites affected by upper gastrointestinal polyposis. ○, Patient with fundic gland polyp(s); ●, patient with adenomas. (From Spigelman *et al.*[23]; reproduced with permission of The Lancet Ltd.)

Polyp distribution and type

Adenomas are distributed throughout the duodenum and small bowel, the majority being found in clusters around and distal to the ampulla of Vater[24,45]. Very few are found proximal to the ampulla compared with the number found in the second part of the duodenum. This distribution of polyps closely mirrors the pattern of mucosal exposure to bile (*Fig. 1*), an observation that has lead to studies relating bile metabolism to the pathogenesis of upper gastrointestinal polyps in these patients[23] (see below).

The macroscopic appearance of duodenal polyps is very different to that of colonic polyps. The number of the former varies from none visible to over 100. They may present as multiple discrete adenomas (1–10 mm in

Table 2 Staging system for severity of duodenal polyposis

	Duodenal disease grading (points)		
	1	2	3
No. of polyps	1–4	5–20	>20
Size of polyps (mm)	1–4	5–10	>10
Histology	Tubular*	Tubulovillous	Villous
Dysplasia	Mild	Moderate	Severe

*Or hyperplasia, inflammation. Stage 0, 0 points; stage I, 1–4 points; stage II, 5–6 points; stage III, 7–8 points; stage IV, 9–12 points

diameter) or as flat confluent plaques[30] (*Figs 2* and *3*). Sometimes no lesion can be seen and the only clinical abnormality is a prominent ampulla, or the mucosa may appear pale and seem to have a white covering which cannot be removed by rubbing[22]. Biopsies of apparently normal mucosa frequently show microadenomas (*Fig. 4*).

Duodenal polyps are microscopically adenomas, whereas most gastric polyps are histologically termed fundic gland. Duodenal adenomas that are small and tubular with minimal dysplastic features are at least risk of undergoing malignant change. The severity of duodenal polyposis can be quantified using a staging system developed by Spigelman and colleagues[23] which relies on clinical and histological assessment of the duodenum to provide a four-stage scoring system. Stages I and II signify mild duodenal polyposis whereas stages III and IV signify severe disease (*Table 2*).

Less than 10 per cent of patients have gastric adenomas. Although lesions which appear clinically to be polyps are found in the stomach of about 50 per cent of patients with FAP, these are mostly areas of cystic hyperplasia[16] on histological examination which, until recently, were thought to have no malignant potential[15,21]. There has, however, been a single case report describing the development of a gastric carcinoma from an area of fundic gland polyposis[46]. When gastric adenomas are present there seems to be a greater amount of bile reflux on scintigraphic duodenogastric reflux scanning[47]. Adenomatous polyps and malignancy have developed in all parts of the upper gastrointestinal tract, including the gallbladder[48] and biliary tree[49], suggesting that the entire intestinal epithelium is at risk in patients with FAP, especially areas exposed to bile[40].

Natural history

At St Mark's Hospital only 10 per cent of 102 patients with FAP undergoing endoscopic surveillance have been shown to develop advanced (stage IV) duodenal polyposis, while less than 20 per cent have very mild (stage I) disease. The remainder are divided equally between stages II and III. Of those patients who had repeat endoscopies (70 patients) over a mean of 40 (range 26–57) months, three developed duodenal cancer, having previously had advanced, but benign, disease. In seven patients the stage of duodenal polyposis also worsened (stage 0 to I in two patients, I to II in two patients, II to III in one patient, and III to IV in two patients). Patients with stage IV disease tend to be older, suggesting that duodenal polyposis is progressive. This is supported by prospective studies which have shown that the degree of polyposis worsens in 16–40 per cent of patients[22,24,50,51]. The changes are more apparent clinically than when histological assessment is taken into account[52].

Histologically confirmed upper gastrointestinal malignancy has developed in 25 patients from 20 families with FAP seen at St Mark's Hospital since 1925. Of these families, three had more than one member and one family had four members affected. The median age at which these cancers were diagnosed was 57 years and age at death was 58 years; these results are similar to those from the Mayo clinic[39]. Patients present with unexplained symptoms of weight loss, anaemia, jaundice or abdominal pain. When symptoms are present the median survival time is shorter, 5·2 months in the authors' series.

The adenoma–carcinoma sequence

Sellner[53] postulated from epidemiological results (differences in age between presentation with benign and malignant neoplasms, the similar ratios by sex and similar relative distributions within the small bowel) that the adenoma–carcinoma sequence was equally valid in the small bowel and duodenum. Case reports of patients with FAP who had been noted to have adenomatous polyps in association with duodenal malignancies also exist[37]. Spigelman *et al.*[54] examined a series of duodenal cancers in 47 patients with FAP and found remnants of adenoma as a component of, or adjacent to, the cancer in 45 of them. Villous adenomas were not surprisingly most commonly found in association with the cancers, highlighting their associated increased cancer risk.

Genetics

APC *mutations*

FAP is caused by germline mutations in one copy of the tumour suppressor gene, *APC*, localized to chromosome 5q22[55,56]. The gene contains 8538 base pairs and codes for a 300-kDa protein. There are 15 exons, 1–14 being small and exon 15 being much larger (6571 base pairs)[57]. The APC protein appears to affect cell adhesion through its association with the cadherin-binding protein, β catenin[58,59]. It is also thought to have a role in the cytoskeleton and thereby in cell division.

Many argue that there is genotype–phenotype correlation in FAP[60–63]. Different mutations result in different lengths of the final protein product which are more likely to have a differential effect on the protein's normal function. There are innumerable problems with demonstrating a sure effect, not least because of difficulties in accurately ascertaining the phenotype and in dealing with selection bias. For example, when counting polyps which should be counted and which ignored: macroscopic and easily visible polyps, those seen with the assistance of dye spray, or those seen at magnifying endoscopy or on histological examination? Does the resultant polyp count reflect the background absolute number or simply the visible growth fraction (the latter perhaps strongly influenced by environmental factors)? These difficulties also apply to ascertaining the true magnitude of duodenal polyposis. Other problems must also be considered. Was the study prospective? Was a side-viewing endoscope used (the equipment makes a difference)? Were random biopsies taken?

Given these caveats, it is thought that colonic polyps are more prevalent when mutations occur between codons 1250 and 1464, and death from colorectal cancer occurs earlier. Mutations at the extremes of the 3′ and 5′ part of the *APC* gene are probably associated with fewer visible polyps and delayed apparent onset of disease[64,65]. Upper gastrointestinal polyps do not appear to be more commonly associated with mutations between codons 1250 and 1464, but there may be family segregation in the occurrence of periampullary malignancy[34]. Preservation of duodenal disease in the absence of severe colonic disease or congenital hypertrophy of retinal pigment epithelium suggests that patients with mutations at any region of the gene are at risk of upper gastrointestinal disease[66]. This implies that in upper gastrointestinal disease there may be additional factors involved, such as other modifying genes or diet, so that gene analysis may not predict those at greatest risk of upper gastrointestinal cancer.

TP53 *mutations*

Mutations of the tumour suppressor gene *TP53* may help transform precancerous lesions to cancer. Overexpression of p53 has been correlated with increasing severity of dysplasia in colonic lesions[67]. The p53 protein can also be measured immunohistochemically, reflecting an increase in expression of *TP53* gene.

Endoscopic biopsies of duodenal polyps from patients with FAP and surgical specimens from upper gastrointestinal tract cancers have been examined for expression of p53[68], and *TP53* and K-*ras* status[69]. All cancers and 32 per cent of adenomas expressed p53, the intensity of staining increasing with dysplasia. The rates of mutation in *TP53* and K-*ras* are similar to those found in the colon, although the actual site of the *TP53* mutation is different, which suggests a different mutating agent, perhaps environmental or dietary. There is marked overexpression of p53 protein compared with the frequency of mutation suggesting functional inactivation of the gene maybe, once again, due to an abnormal cellular environment. It is possible that detecting overexpression of p53 protein will alert doctors to the need for more frequent surveillance.

Possible role of bile

Polyp distribution mirrors mucosal exposure to bile, suggesting a role for bile in duodenal adenoma development[23]. Several mechanisms are possible: increased mucosal absorption of carcinogens, mucosal damage leading to reactive hyperplasia with cell proliferation and an increased risk of a mutation[70], and supply of genotoxic compounds leading to second hit mutations of the *APC* gene (*Fig.* 5).

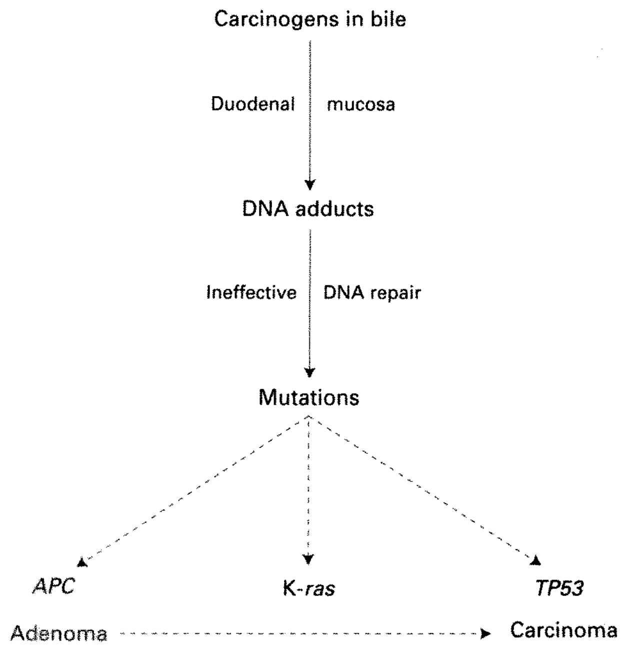

Fig. 5 Schematic representation of the role of DNA adducts in adenoma formation

DNA adducts are electrophilic molecules which bind covalently to DNA and, when not repaired, may lead to mutation and cancer. ^{32}P postlabelling detects DNA adducts and so acts as a fingerprint for the presence of mutating compounds, which may be of unknown composition and be present in very small quantities[71]. Human bile forms four major and characteristic adduct spots when it interacts with DNA. Duodenal mucosal biopsies from patients with FAP show these characteristic spots in much greater quantities[70]. These adduct spots are not simply the result of poor DNA repair in patients with FAP because they are seen when animal small intestine is challenged with FAP bile[72] and when DNA is mixed with FAP bile in a test tube[73]. Control bile from patients without FAP produces fewer adduct spots under these conditions. Furthermore, transgenic mice containing a mutation in the *Apc* gene also have bile which produces the same adduct pattern when incubated with DNA *in vitro*[74]. When FAP bile is incubated with human cell lines *in vitro* some mutagens require metabolic activation and some act directly. Adduct labelling also appears to be pH sensitive between a narrow band at pH 4–5, leading to therapeutic possibilities for upper gastrointestinal polyp prevention or treatment of FAP using antacids (see below)[75].

Pure biliary acids do not produce DNA adducts[76]. Bile *in vivo* is a complex mix of many substances other than bile acids and the finding of characteristic adduct spots and excess amounts of DNA adducts in FAP lends strong support to the presence of a biliary mutagen activated at a low pH. Perhaps the finding of abnormal liver metabolism of some carcinogens in FAP by glutathione S transferase mu[77], *N*-acetyltransferase and CYP 1A2[78] may go some way to explaining why polyposis bile is different.

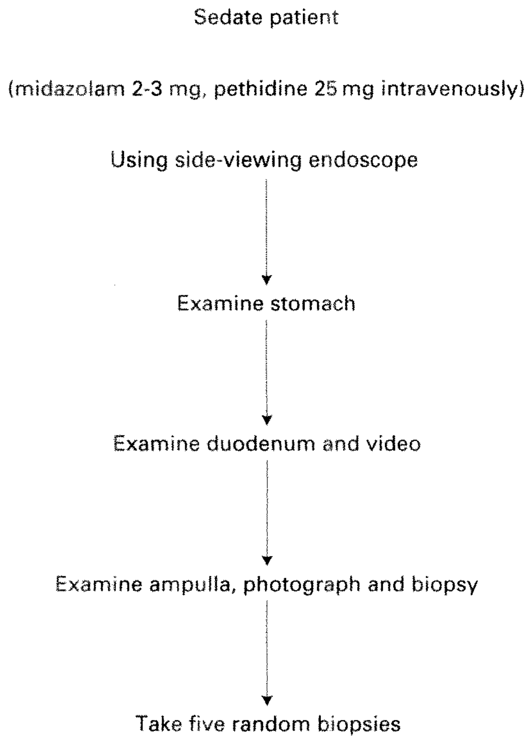
Bile acids themselves also interact with second messenger signalling systems which are activated in colorectal cancer and, perhaps, in upper gastrointestinal cancer. One method is through the release of arachidonic acid and the production of prostaglandin E_2[79]; a second is through the protein kinase system, known to be activated in colonic adenomas and carcinomas[80]. These signalling systems are closely involved in controlling cellular proliferation and so in tumour development. Studies in patients with FAP that have shown different concentrations of individual bile acids, perhaps as a result of total colectomy and altered secondary bile acid metabolism, may mean that the above mechanisms might be important in upper gastrointestinal polyposis in FAP[81–84].

Treatment

Endoscopic surveillance

Regular endoscopic surveillance at intervals of 6 months of the retained rectal stump after ileorectal anastomosis is routine to detect cancer and permit prompt treatment. As more about upper gastrointestinal disease in FAP is learned, the question of surveillance of the upper gastrointestinal tract must be readdressed with respect to: patient comfort and through this acceptance of repeated examination, maximization of information through videotaped side-viewing endoscopy (which permits proper evaluation and recording of the ampulla, the most commonly affected site[22,23]) with the generous use of biopsy, and the frequency of re-examination (which can only be considered in the light of therapeutic options).

Duodenoscopy with a side-viewing instrument is often unpleasant for the patient. Given the need for repeated re-examination, these patients are not suitable for training of the inexperienced clinician as they may default from further follow-up (and may even refuse rectal surveillance in the future as well). Patients should be well sedated and examination should follow a routine (*Fig. 6*). Endoscopy is relatively safe, although complications such as pancreatitis have been reported when multiple biopsies of the periampullary area are taken[85].



Sedate patient
(midazolam 2-3 mg, pethidine 25 mg intravenously)
Using side-viewing endoscope
Examine stomach
Examine duodenum and video
Examine ampulla, photograph and biopsy
Take five random biopsies

Fig. 6 Suggested protocol for upper gastrointestinal endoscopy in patients with familial adenomatous polyposis

Endoscopic ultrasonography may help when confronted by a huge or plaque-like polyp. Not only may it allow better selection of patients with invasive but operable lesions[86], it may also show lack of invasion in some cases, permitting further follow-up examination in 6 months rather than open surgery[87].

Treatment options

The aim is to control duodenal polyposis and thereby prevent the development of malignancy. The outcome after surgery for already established duodenal, periampullary or pancreatic malignancy is relatively poor. For example, the mean postoperative survival of patients with periampullary or duodenal cancer is 2 years for all stages of the disease[88]. The best results of 85 per cent 5-year survival occur only if the lesion is confined to the sphincter of Oddi[89].

Surgery. Surgical control by duodenotomy and mucosal excision of lesions seems at first sight a sensible preventative precaution when confronted by advanced but not invasive duodenal polyposis[90]. Review of 12 patients at St Mark's Hospital and the Hôpital St Antoine in Paris with stage IV polyposis, treated by duodenotomy and clearance, showed 100 per cent recurrence within 13 months of surgery[91]. Although this is not surprising in view of the presence of microadenomas, it makes management of advanced but non-invasive duodenal polyposis uncertain. This is why a case can be made for endoscopic ultrasonography and, in the absence of evidence of invasion, further surveillance in 6 months. Alternatively, duodenal excision by pancreas-sparing duodenectomy[92] may be suggested but this, and the even more aggressive Whipple's procedure, have such high associated morbidity and mortality rates that their application for benign disease may be questioned[93,94].

Endoscopy. Endoscopic control of duodenal polyps by snare excision or diathermy might seem obvious and easy[95]. However, duodenal polyps are often confluent, flat, plaque-like lesions, rather than discrete raised polyps, making snaring almost impossible (*Fig. 3*). Repeated periampullary diathermy may scar and narrow the ampulla, potentially leading to pancreatitis, haemorrhage, and future difficulties with clinical and histological assessment.

Photodynamic therapy. Photodynamic therapy (PDT) is a non-thermal means of inducing localized necrosis with light after administration of a photosensitizing drug. To treat gastrointestinal tract lesions, the photosensitizer must be given systemically, with the light delivered to the target area endoscopically. Good healing of PDT-treated lesions makes this approach at first glance attractive. However, although a range of photosensitizing drugs has been assessed by many groups, all have the drawback that patients may be left sensitive to bright light for several weeks after treatment[96,97]. Furthermore, treatment with PDT requires repeated application to remove all initial polyps followed by maintenance therapy. Photosensitivity and need for repeated treatment lessens the suitability of PDT. Even greater drawbacks, however, are the very superficial depth of necrosis achieved, the long illumination time required to treat each lesion, and the large numbers of lesions that need treatment in patients with clinically important upper gastrointestinal disease[98].

Argon plasma coagulation. Argon plasma coagulation is a method of non-contact electrocoagulation in which current is applied to tissue by means of ionized argon gas (argon plasma) that can be delivered endoscopically[99]. Coagulation depth is limited to 2–3 mm, resulting in controlled tissue trauma and reduced risk of perforation or bleeding[100]. This technique may be of future use in FAP.

Sulindac. Both retrospective and prospective clinical studies have suggested that non-steroidal anti-inflammatory drugs (NSAIDs) may protect against gastrointestinal cancer[101–103], an observation also made in animal studies[104]; the exact mechanism of action is unknown. NSAIDs inhibit cyclo-oxygenase (COX) which converts arachidonic acid to prostaglandins, thromboxanes and prostacyclins. These prostaglandins may affect cell proliferation and tumour growth through activation of second messenger systems, as they have been found in significant quantities in several cancers, including adenocarcinomas[105]. NSAIDs have also been shown to inhibit cell proliferation, presumably through their inhibitory affect on COX.

There are two COX enzymes in humans, COX-1 and COX-2. Animal studies in mice with mutations in the *Apc* gene showed that polyp regression occurred when COX-2 activity was suppressed, providing direct evidence that COX-2 plays a key role in tumorigenesis in an FAP animal model[106]. Most NSAIDs suppress both COX-1 and COX-2 activity and, although not specific in their action, appear to have an inhibitory effect on tumour development. Gastrointestinal side-effects caused by NSAIDS seem to be mediated through COX-1 inhibition, so there may be clinical value in the development of selective COX-2 inhibitors.

The first report that the NSAID sulindac might affect rectal adenomas in FAP was in 1983[107]. Since then several trials have shown benefits when using sulindac to control not only rectal[108,109] and duodenal[110], but also desmoid[111], disease. A randomized controlled trial of the effect of sulindac on duodenal polyps showed regression of early adenomas[112], but there was no reduction in the size of larger adenomas[110], perhaps as the latter had further genetic change, such as *TP53* mutation[68], which might have made them unresponsive. Indices of cell proliferation were also reduced[110,113]. Others have found in the rectum that reduction in polyp size is only partial and depends on the length of treatment[114], and that withdrawing the drug results in recurrence of the adenomas[109]. However Winde *et al.*[108], using sulindac suppositories, have claimed complete and long-term suppression with a low dose of 67 mg/day. Whatever the reality, it seems that large polyps are relatively unresponsive and cancer still occurs in patients with polyp regression[115,116].

Sulindac is the only medication so far which has shown any measurable effect on duodenal polyposis. Drugs such as calcium[117], vitamin C[118] or starch[119] have been evaluated in patients with FAP, but they have had no demonstrable effect on duodenal disease[120]. There are several clinical trials currently under way examining the effects of various modified NSAIDs in the duodenum of patients with FAP.

Antacids. The observation that DNA adducts form at a more acid pH raises the question as to whether some form of acid lowering therapy might influence duodenal disease in FAP. One randomized placebo controlled trial is currently under way and should answer this question.

Conclusion

Surgeons treat the large bowel component in polyposis either by colectomy and ileorectal anastomosis or by restorative proctocolectomy. Thereafter, upper gastrointestinal disease becomes an increasingly important problem in patient management. For large bowel disease there is a virtual 100 per cent risk of cancer if left untreated, but for upper gastrointestinal disease only about 5 per cent of patients will develop cancer, despite 90 per cent or more having adenomas.

As the best management of upper gastrointestinal disease is not yet known, frequent surveillance seems inappropriate. Currently at St Mark's Hospital endoscopy is commenced at age 25 years, with lesser degrees of polyposis being screened at intervals of 5 years. For more advanced disease, the screening frequency is increased, sometimes to intervals of 6 months. When confronted by a case of advanced duodenal polyposis the choice lies between continued surveillance or surgical clearance; there are substantial problems with either decision.

The long-term answer surely lies with some form of drug therapy. At the moment modified NSAIDs and antacids are being tried, but in the future gene therapy[121] may have a place, particularly if a delivery system via the biliary tree is devised. Port access through the gallbladder would allow liposomes containing normal *APC* to transfect cells mucosally exposed to bile, thus targeting the exact distribution of upper gastrointestinal adenomas.

Background The advantages of pancreatogastrostomy over pancreatojejunostomy after pancreaticoduodenectomy are still debated. This study analyses the results of pancreatogastrostomy to identify factors that could influence immediate outcome.

Methods During a 10-year period, 160 consecutive patients underwent a pancreatogastrostomy. There were 109 men (68 per cent) and 51 women (32 per cent) with a mean(s.d.) age of 59(10) (range 22–82) years; 27 patients were older than 70 years. The following parameters were assessed: mortality rate, morbidity, reasons for reoperation, length of hospital stay, duration of nasogastric tube and drainage.

Results Hospital mortality rate was 3 per cent; overall morbidity rate was 30 per cent. The reoperation rate was 12 per cent, mainly because of bleeding at the pancreatic margin. Delayed gastric emptying occurred in 36 patients. The overall rate of pancreatic fistula was 2·5 per cent. Age, sex, indications for pancreatoduodenectomy, and the texture of the pancreatic remnant did not influence the occurrence of pancreatic fistula or delayed gastric emptying.

Conclusion This study confirmed that pancreatogastrostomy is a safe procedure with low mortality and morbidity rates.

Since 1990, several authors have reported a postoperative mortality rate of less than 8 per cent after pancreatoduodenectomy, and some have achieved nil mortality[1–9]. Surgical experience, patient selection and the decrease of postoperative morbidity undoubtedly represent the main factors explaining this dramatic reduction[1–4]. Given that morbidity is often related to the occurrence of pancreatic fistula[10], it is essential to work towards the reduction of this risk.

Recently published studies[11–19] have emphasized the advantages of pancreatogastrostomy although firm conclusions cannot be drawn because of the retrospective nature of the studies and/or an insufficient number of patients.

In the present study the results of pancreatogastrostomy were collected prospectively for 160 consecutive patients during a 10-year period and assessed to identify factors that could influence immediate outcome.

Patients and methods

A total of 160 consecutive patients underwent pancreatogastrostomy after pancreaticoduodenectomy between 1987 and 1996. There were 109 men (68 per cent) and 51 women (32 per cent) with a mean(s.d.) age of 59(10) (range 22–82) years; 27 patients were older than 70 years. The indications for operation are listed in *Table 1*.

After resection, a hand-sewn pancreatogastrostomy was carried out through a posterior gastrostomy with one layer of interrupted sutures (3/0 polyglactin). When the pancreatic duct was not dilated it was stented to avoid occlusion.

Oral intake was permitted the day after removal of the nasogastric tube. Drains were removed progressively according to the amount of fluid recovered. A pancreatic fistula was defined as the recovery of more than 50 ml of amylase-rich fluid (more than five times the normal plasma levels) from the drain site during the postoperative period. The fistula track was confirmed radiologically with water-soluble contrast agents. Delayed gastric emptying was defined as the presence of a nasogastric tube more than 10 days after surgery, or its reinsertion because of vomiting.

Statistical analysis

All data were collected prospectively. The following parameters were assessed: mortality, morbidity, reasons for reoperation, length of hospital stay, duration of nasogastric tube and drainage.

Student's *t* test and χ^2 test were used for statistical analysis. A univariate analysis was carried out to compare patients with and without delayed gastric emptying and/or pancreatic fistula.

Results

Pathological examination of the pancreatic resection margin was negative in 127 patients (79 per cent), showed

Table 1 Indications for pancreaticoduodenectomy

	n
Pancreatic duct cancer	69 (43)
Cancer of the ampulla	24 (15)
Chronic pancreatitis	21 (13)
Distal bile duct cancer	13 (8)
Mucinous ductal ectasia	5 (3)
Serous cystadenoma	5 (3)
Mucinous cystadenoma	3 (2)
Pseudocyst of the pancreas	3 (2)
Duodenal adenocarcinoma	3 (2)
Islet cell tumour	2 (1)
Pancreatic trauma	2 (1)
Miscellaneous	10 (6)
Total	160 (100)

chronic pancreatitis in 25 (16 per cent) and tumour foci in eight (5 per cent). The texture of the pancreas remnant was considered normal in 113 patients (71 per cent) and fibrotic in 47 (29 per cent).

The hospital mortality rate was 3 per cent ($n = 5$). Causes of death were multiple organ failure ($n = 2$), myocardial infarction ($n = 1$), sepsis ($n = 1$) and pneumonia ($n = 1$). The overall morbidity rate was 31 per cent ($n = 49$). Complications requiring reoperation in 19 patients (12 per cent) included: haemorrhage at the pancreatic margin ($n = 7$), wound dehiscence ($n = 3$), pancreatic fistula ($n = 2$), haemoperitoneum ($n = 2$), intestinal obstruction ($n = 1$), thrombosis of the mesenteric vein ($n = 1$), biliary leak ($n = 1$), necrosis of the pancreatic remnant ($n = 1$) and wound infection ($n = 1$).

Complications managed conservatively in 30 patients (19 per cent) included: delayed gastric emptying ($n = 20$), fistula at the gastrojejunostomy ($n = 3$), pancreatic fistula ($n = 2$), intra-abdominal abscess ($n = 10$), bile leak ($n = 1$), pneumonia ($n = 1$), liver abscess ($n = 1$) and wound infection ($n = 1$).

The overall rate of delayed gastric emptying was 22 per cent ($n = 36$). Thirteen patients had a nasogastric tube in place for more than 10 days and nine patients for more than 20 days.

Univariate analysis showed that patients with or without delayed gastric emptying were similar in age, sex, indications for pancreaticoduodenectomy and texture of the pancreatic remnant. The reoperation rate was significantly higher ($P < 0{\cdot}0001$) and the mean hospital stay longer ($P < 0{\cdot}0001$) in patients with delayed gastric emptying than those without.

The overall rate of pancreatic fistula was 2 per cent ($n = 4$). The comparison of patients with pancreatic fistula *versus* those without pancreatic fistula failed to reveal significant predictors. Mean length of hospital stay was 10 days longer in patients with pancreatic fistula ($P < 0{\cdot}02$).

Mean(s.d.) length of hospital stay was 22 (9) days. The mean duration of abdominal drainage was 8 (range 0–37) days.

Discussion

Pancreatic fistula following pancreaticoduodenectomy has been considered a serious event with a frequency varying from 10 to 30 per cent. Moreover, it has been a life-threatening condition responsible for death in one-half or one-third of patients[10]. Consequently, many technical variations have been described to improve quality and safety of the pancreatic anastomosis, either with new techniques of pancreatojejunostomy[20–22], by reinforced anastomosis with fibrin glue sealing[23], the avoidance of the anastomosis with occlusion of the pancreatic duct[24,25], the use of octreotide to reduce pancreatic secretion[26,27], or with the achievement of a pancreatogastrostomy. The feasibility of the latter has been demonstrated in experimental studies[28] and humans[29].

Considering the literature of the past 5 years, the authors noted that the rate of pancreatic fistula remained stable, but related fatal complications have decreased significantly (*Table 2*). In the same period a few single institutional reports underlined the safety of pancreatogastrostomy (*Table 3*) and some reported no pancreatic fistula[12,14,17,19]. Although these encouraging results should be evaluated in the light of selection bias (retrospective analyses and limited numbers of patients), a new impetus was offered to this old surgical technique.

The authors began using pancreatogastrostomy in 1987. It then became the standard procedure in the department for all patients referred for pancreaticoduodenectomy whatever the indications for operation, age and status of the patient, texture of the remnant pancreas and intra-operative difficulties encountered. This operation was always carried out by senior surgeons experienced in pancreatic surgery.

Some technical details are noteworthy: (1) the left pancreas must be freed from the splenic vein to allow it to lie upright without strain towards the posterior gastric wall; (2) perfect haemostasis of the pancreatic remnant is essential; (3) the insertion of the pancreas stump through a short gastrostomy secured with one layer of absorbable interrupted stitches; and (4) insertion of a thin catheter in a non-dilated pancreatic duct to prevent it being closed during the anastomosis. Following these rules, the edge of the pancreatic stump must protrude in the gastric lumen by 2–3 cm, which is easily checked during gastro-enterostomy.

In the present study the hospital mortality rate was 3 per cent which compared favourably with that of a comprehensive review of the literature (*Table 3*). Moreover, it is also comparable to that reported in recent series including more than 100 pancreatoduodenectomies with a

*Patient reoperated for complication.

majority of pancreatojejunostomy (*Table 2*). Thus, pancreatogastrostomy did not impair the expected results of pancreatoduodenectomy.

The reoperation rate was 12 per cent (19 of 160). The major cause of reoperation was upper gastrointestinal haemorrhage (seven of 19); the diagnosis is evident and prompt reoperation is often required. This particular complication represents 3 per cent of patients in the review. Trede *et al.*[9] reported such complications in 4 patients after 118 consecutive pancreatoduodenectomies (107 Whipple and 11 total resections). However, in these cases haemorrhage was mostly located at the gastroenterostomy and not on the site of the pancreatojejunostomy. In the experience of the authors haemorrhage was often related to small bleeding arteries located on the pancreatic edge. Whether pancreatogastrostomy increases the risk of postoperative digestive haemorrhage is questionable. It could be hypothesized that the gastric lumen is larger than the jejunal lumen and does not favour spontaneous clotting. Consequently, perfect haemostasis of the pancreatic stump is required, preferably with stitches rather than electrocoagulation and should be checked from inside the stomach during the gastroenterostomy. Other authors[13] have also attached importance to rigorous haemostasis of the gastric submucosa. During reoperation bleeding was always easy to control with stitches applied to the pancreatic surface through an anterior gastrotomy.

Postoperative pancreatic fistula was a rare event in the study but two required reoperation. This low rate of pancreatic fistula (2 per cent) compares favourably with those of the comprehensive review. No death was related to pancreatic fistula, but hospital stay was significantly longer.

Other studies[7,8] have highlighted numerous factors as determinant parameters of pancreatic fistula. Texture of the remnant pancreas, size of the pancreatic duct and the surgeon's experience were reported as the most significant parameters[34,35].

In retrospective comparative studies between pancreatojejunostomy and pancreatogastrostomy the results concerning the risk of pancreatic fistula are conflicting[35,38]. Some authors have pointed to the safety of pancreatogastrostomy lessening the number of pancreatic fistulas[19,37,38]; others have denied this assertion[8]. In a recent prospective randomized study the occurrence of pancreatic fistula was not significantly influenced by the type of anastomosis[34].

In fact the most problematic postoperative complication noted in this study was delayed gastric emptying (22 per cent). The rate of this complication following pancreaticoduodenectomy ranges from 20 to 50 per cent, particularly after pylorus-preserving procedures[1,2]. The majority of patients in this study underwent partial gastrectomy rather than a pylorus-preserving operation and no difference was noted between the two techniques. The cause is unknown and can occur in the absence of medical or surgical complications as noted in two-thirds of the present patients complaining of delayed gastric emptying. To the authors' knowledge there is no published study evaluating the role of the pancreatogastrostomy on gastric motor function. In their comparative study Yeo *et al.*[34] reported a comparable rate of delayed gastric emptying (22 per cent) after either pancreatojejunostomy or pancreatogastrostomy. Long-term functional outcome of pancreatogastrostomy after pancreatoduodenectomy is rarely evaluated because this procedure is often proposed for patients with pancreatic malignancy. Theoretically the lack of enterokinase in the gastric mucosa prevents the activation of pancreatic enzymes lessening the risk of pancreatic duct stenosis[39]. Pain and Knight[40] noted a higher incidence of steatorrhoea in patients undergoing pancreaticogastrostomy for duct drainage chronic pancreatitis. Johnson[41] demonstrated the presence of pancreatic enzymes in response to hormones and normal gastric secretion many years after operation.

In conclusion this study confirmed that pancreatogastrostomy is a safe procedure with low mortality and morbidity rates. Further prospective randomized studies are required to clearly define whether pancreatogastrostomy is a real improvement or a fashionable procedure. Undoubtedly these studies should be reserved for specialized centres that have carried out a large volume of pancreatic resections, have experienced surgeons, and where the mortality and pancreatic fistula rates are less than 5 per cent.

Background Percutaneous computed tomography (CT)-guided aspiration of abdominal collections is performed in necrotizing pancreatitis to detect infection of necrosis, which is an adverse prognostic factor and requires surgical drainage. However, in the case of sterile aspirates, the outcome and the optimum management are subject to debate. This study examined the clinical and bacteriological outcome of patients with severe acute pancreatitis with initially sterile necrosis and assessed the efficiency of percutaneous drainage in this setting.

Methods Seventeen patients hospitalized for necrotizing pancreatitis with a septic course underwent a preliminary sterile CT-guided aspiration. Eight patients underwent simultaneous percutaneous drainage of the punctured collection. Supportive therapy was continued unless severe clinical deterioration or proven secondary infection of necrosis indicated the need for necrosectomy and drainage.

Results Secondary infection of necrosis was observed in two patients of nine who had only fine-needle aspiration cytology of the collection, and in seven of eight it was drained percutaneously ($P = 0 \cdot 01$). Only one patient drained percutaneously recovered without surgery. Surgical drainage was required in 12 patients. The hospital mortality rate was 29 per cent and was not significantly affected by the bacteriological status of necrosis.

Conclusion Percutaneous drainage of sterile collections predisposed to secondary infection of the necrosis and did not cure the patients. A first sterile percutaneous aspiration did not predict a favourable course and surgery frequently remains necessary.

Despite improvements in intensive care management, imaging techniques, and surgical strategies, the mortality rate of necrotizing pancreatitis is still 8–35 per cent[1,2]. Since the work of Beger *et al.*[3], infection of necrotic pancreatic and peripancreatic tissues has been widely recognized as a strong adverse prognostic factor. Infection of necrosis complicates the course of about 30 per cent of necrotizing pancreatitis[4], and can be now diagnosed by percutaneous computed tomography (CT)-guided aspiration[5,6].

There is general agreement that infected pancreatic necrosis is an absolute indication for surgical drainage[6–8]. Pancreatic abscesses and fluid collections associated with necrosis can be drained percutaneously[9,10]. In contrast, the evolution and management of sterile necrosis remain controversial[11]. Overall mortality has been reported in sterile necrosis to be 0–36 per cent[1,7,12], and some authors advocate surgical abstention[7], whereas others favour drainage of symptomatic collections, irrespective of their bacteriological status[13].

To assess the bacteriological and clinical evolution of patients presenting with initially sterile necrosis and the efficiency of percutaneous drainage of sterile collections, the records of patients admitted for necrotizing pancreatitis with a sterile CT-guided percutaneous aspiration were studied.

Patients and methods

Between June 1985 and May 1995, 269 patients with acute pancreatitis were admitted. According to the clinical course, CT scans and operative reports, 71 patients were considered to have necrotizing pancreatitis and were treated in an intensive care unit. Because of clinical suspicion of infected necrosis, based on temperature of over 38·5°C and leucocytosis of more than 10 000 per mm^3, unexplained by another source of sepsis, 48 patients underwent an initial CT-guided percutaneous aspiration of intra-abdominal collection or mass to provide samples for bacteriological analysis. In 31 patients, bacteria were found in the aspirated material. In this group of patients 27 were operated on: 19 had infected necrosis, six had pancreatic abscess and two had sterile necrosis. In the four remaining patients, pancreatic abscesses were drained percutaneously and no operation was required. The mortality rate in this group was 12 of 31. In 17 patients the material collected from percutaneous aspiration was sterile.

The remaining 23 patients who had no percutaneous drainage or puncture had a complicated course. Two patients died before operation on day 3 after onset of pancreatitis. The other patients were operated on: 13 had infected pancreatic necrosis, four had sterile necrosis, four had a pancreatic abscess. Sixteen of the 23 patients were referred from other centres and 12 had been operated on. The mortality rate in this group was nine of 23. In this group of patients percutaneous aspiration was not performed either because the diagnosis of infected necrosis was already made or because percutaneous aspiration was judged technically difficult or dangerous.

Computed tomography

Contrast-enhanced CT scans were taken to delineate extrapancreatic collections and necrosis of the pancreas itself (necrosis was suspected when there were non-enhanced areas of less than 40 Hounsfield units[7], and was classified by the radiologist as absent or affecting less or more than 50 per cent of the gland). All CT scans were graded according to Balthazar's classification[14]. Only collections with safe percutaneous access were aspirated. A part of the fluid aspirated was Gram stained

Paper accepted 30 September 1997

and immediately analysed by the bacteriologist, whereas the remainder was cultured for aerobic or anaerobic bacteria and fungus. At the beginning of the authors' experience, without waiting for the results of bacteriological examination, a single-lumen pigtail drain (14-Fr) was inserted frequently in the fluid collections after dilatation of the needle track, and left in place for prolonged drainage.

Study group

In 17 patients the first percutaneous aspiration provided sterile material, in eight of whom a pigtail catheter was left in the collection. Only bacteriologically proven infection of non-drained necrosis or severe clinical deterioration with a septic state uncontrolled by supportive treatment prompted surgical drainage with necrosectomy.

The clinical, biological, bacteriological and radiological data of the 17 patients who initially had sterile necrosis, were collected prospectively and constituted the basis of this study. There were 11 men and six women with a median age of 53 (range 41–71) years. The cause of pancreatitis in nine patients was alcohol abuse, biliary lithiasis in six patients, endoscopic spincterotomy in one and unknown in one. The median Ranson[15] score was 4 (range 2–8). Patients were hospitalized with a median delay of 6 (range 0–23) days after the onset of symptoms.

The clinical status of the patients in the 24 h preceding the percutaneous aspiration was assessed by the Simplified Acute Physiology Score (SAPS) which evaluates the risk of death in patients in the intensive care unit[16]. Bacteriological examination of iterative percutaneous CT-guided aspiration, fluids drained by percutaneous pigtail drains, and fluids or necrosis yielded peroperatively were recorded.

Statistical analysis

Statistical analysis was performed using Fisher's exact test (two-tail). $P < 0{\cdot}05$ was considered significant. Values are expressed as mean(s.d.) or median(range).

Results

Clinical status and biochemical parameters preceding percutaneous aspiration

CT-guided percutaneous aspirations were performed a mean(s.d.) of 16(7) days after the onset of pancreatitis. Mean(s.d.) SAPS was 8·6(2·4) (expected mortality rate 20 per cent). Abdominal guarding and ileus were noted in one-half of the patients and encephalopathy was observed in a single patient. Hypocalcaemia was noted in six patients. Serum amylase concentration showed a wide range of values (22–2127 units/l), and was still raised (over 100 units/l) in 13 patients.

CT scan and percutaneous aspiration

All patients had a grade E (2–6 fluid collections) contrast-enhanced CT scan. A non-enhanced pancreatic area involved less than one-half of the gland in nine patients and more in five. Three patients had only peripancreatic collections and necrosis was proven later by surgery or autopsy. A pleural effusion was present in ten patients. Aspirated collections were located in the lesser sac in 11 patients and in the left pararenal anterior space in six. These locations were encountered most frequently (*Table 1*) and were frequently associated with a third collection located in the mesentery, which was not punctured because of vascular risk. A pigtail drain was left in place in eight patients. During the hospital course, seven patients underwent a second percutaneous aspiration of the same collection and two of them had a third aspiration of the same persisting collection. Among the eight patients treated by percutaneous drainage of initially sterile collections, two patients had a second percutaneous drain insertion and one patient underwent a third percutaneous drainage.

Bacteriological findings

Five patients had received antibiotics intravenously for more than 24 h when the first percutaneous aspiration was performed.

Nine patients developed a secondary infection of necrosis during their hospital stay (*Table 2*). Secondary infection was proven by peroperative bacteriological sampling in case of surgical drainage or, if the patient was not operated on, by bacteriological analysis of the material harvested by iterative percutaneous aspiration or drain. Secondary infection was observed in two of nine patients who had only fine-needle aspiration cytology (FNAC) of the sterile collection *versus* seven of eight patients who underwent percutaneous drain insertion ($P = 0{\cdot}01$) (*Table 2*). Secondary infections were diagnosed after a median delay of 15 (range 2–53) days after the initial sterile percutaneous aspiration (*Fig. 1*). Bacteria encountered are listed in *Table 3*.

Treatment and outcome

Of the nine patients treated without percutaneous drainage two were treated without surgery; one recovered and one died from sudden irreversible multiple organ failure (MOF) without bacteriologically proven sepsis.

Table 1 Location of intra-abdominal extrapancreatic collections on computed tomographic scans

Location of collection	No. of patients
Lesser sac	17
Left anterior pararenal space	14
Mesentery	12
Transverse mesocolon	3
Left posterior pararenal space	2
Right anterior pararenal space	2
Right posterior pararenal space	1
Pelvis	1

Two of six collections per patient were observed on computed tomographic scan

Table 2 Micro-organisms found in the necrotic collections by percutaneous aspiration, percutaneous drainage or surgical sampling

Gram stain	Micro-organism	No. of patients
Gram-negative	*Pseudomonas aeruginosa*	3
	Klebsiella oxytoca	2
	Escherichia coli	1

Drainage ($n = 8$)	No surgery ($n = 3$)	Infected ($n = 3$)	1
	Surgery ($n = 5$)	Sterile ($n = 1$)	0
		Infected ($n = 4$)	1

Bacteriological outcome was defined by: (1) bacteriological results of the analysis of the last aspiration performed or the analysis of the fluids drained by a percutaneously inserted pigtail drain if the patient was not operated; (2) bacteriological analysis of the samples harvested during operation if the patient underwent surgical drainage and necrosectomy. CT, computed tomography

Seven patients ultimately required surgical drainage and necrosectomy.

Among the eight patients treated initially with percutaneous drainage two recovered despite a secondary infection of the drained collection (one without sequelae and one with a late pseudocyst treated by surgical cystogastrostomy), one patient died from septic shock 48 h after the percutaneous drainage with a secondary staphylococcal infection of the initially sterile drained collection, and five patients ultimately required surgical drainage and necrosectomy.

Thus, in the whole series, two patients died among the five who were not operated on and 12 patients ultimately underwent surgical drainage and necrosectomy. Operation was performed after a median delay from the initial aspiration of 14 (range 3–53) days (*Fig. 1*). The indications for surgical treatment are detailed in *Table 4*. Before operation, infection of necrosis was proven or only suspected because of Gram-negative bacteria in blood cultures from five patients, and was confirmed during operation in four. Among seven patients without preoperative proof of infection, necrosis found during operation was sterile in five patients and infected in two. Three patients died after surgery, two from sepsis and one from pulmonary embolism accounting for a surgical mortality rate of 25 per cent. Eight patients required several surgical procedures (range 2–4) during their initial stay and later readmissions to treat biliary lithiasis, pseudocyst or fascial disruption.

Table 4 Indications for surgical drainage

Status before operation	No. of patients	Proven infection of necrosis
Sepsis syndrome and positive percutaneous aspiration	3	2
Sepsis syndrome and positive percutaneous drainage	1	1
Sepsis syndrome and positive blood culture	1	1
Sepsis syndrome and gastrointestinal tract haemorrhage	3	1
Sepsis syndrome and one or more altered vital function	4	1

Sepsis syndrome was defined by the conjunction of fever over 38·5°C, white blood cells of more than 10 000 and, in some cases, a septic haemodynamic profile. Infection of necrosis was proven by peroperative bacteriological sampling systematically collected

The mortality rate of 25 per cent (two of 18) in the group of patients initially drained percutaneously did not differ significantly from the 33 per cent (three of nine) mortality rate observed in the group of patients treated without percutaneous drain insertion. Among the eight patients with sterile necrosis, two died. Among the nine patients with secondarily infected necrosis, three died. The mean stay in intensive care unit for survivors was 63 (range 23–114) days.

Discussion

In this series, percutaneous aspiration was always performed in severe pancreatitis as recommended by Gerzof *et al.*[6]. The median Ranson score was high, and the bioclinical status of the patients during the 24 h preceding the aspiration assessed by the SAPS indicated an expected mortality rate of 20 per cent. The severity of the pancreatitis was also demonstrated by CT scans showing grade E lesions in all patients[14] and the presence on CT scan of non-enhanced pancreatic areas[7,17] in 13. The 35 per cent rate of first sterile aspiration (17 of 48) observed in patients is comparable to the 40 per cent rate reported by Gerzof *et al.*[6].

The severity of the initial bioclinical status accounts for the length of hospital stay and the overall mortality rate of 29 per cent observed in this series of initially sterile necrotic pancreatitis. Karimgani *et al.*[12] recently reported

26 patients whose necrosis remained sterile throughout their hospital course with a mortality rate of 38 per cent.

Prolonged percutaneous drainage of initially sterile collections led to secondary infection of drained collections in seven of eight patients confirming recently published data[18]. Nevertheless, percutaneous drainage did not significantly increase mortality, compared with patients without percutaneous drain insertion. Among the eight patients drained percutaneously, only two recovered without surgical necrosectomy and one of them developed a late pseudocyst requiring surgical cystogastrostomy. This observed failure of percutaneous drainage and the infection rate prompted the abandonment of this therapeutic modality in patients with sterile collections, as done previously in case of pancreatic abscess[8]. The current policy is to perform percutaneous aspiration during the first CT examination in order not to overlook a pancreatic infection. If the bacteriological cultures are sterile medical supportive treatment is continued. CT scans are performed every week with routine aspiration, or sooner when a clinical event (organ failure, increased white cell count) suggests pancreatic infection. When bacteria are found patients undergo operation.

Despite a policy of initial conservative treatment of sterile necrotizing pancreatitis, 12 of 17 patients underwent operation during hospital stay because of infection of necrosis or because of severe bioclinical deterioration. These results differ markedly from those of Bradley and Allen[19] who reported a series of 11 patients with sterile necrosis, all successfully treated without surgery. However, their patients had less extended pancreatic necrosis involving a mean(s.d.) of 38(4) per cent of the gland, and five of them did not undergo CT-guided percutaneous aspiration because they had a straightforward clinical course. The present results differ also from the series of 50 sterile aspirations reported by Gerzof *et al.*[6] in which necrosis remained sterile in all cases, compared with secondary infection which occurred in nine of the present patients, two of whom did not undergo percutaneous drainage. After a first sterile aspiration, secondary infection of pancreatic necrosis can be explained, either because the first puncture was performed before subsequent infection, or by the coexistence of separate sterile and infected collections in the same patient accounting for a false-negative rate of FNAC of 10 per cent[13,20]. The use of antibiotics causing high pancreatic tissue concentration[21] may also impair bacteriological analysis.

The 29 per cent overall mortality rate observed in this series of initially sterile necrosis was comparable to the mortality rates reported for infected necrosis[2,3,13,22,23]. Furthermore, the patients secondarily infected in this series did not have a worse prognosis than the patients whose necrosis remained sterile, as recently reported by Rattner *et al.*[13]. This questions the true role of infection of necrosis commonly considered to be a strong adverse prognostic factor[3,24]. This study was not multivariate, but analysis reveals that the extent of pancreatic and extrapancreatic necrosis was a prognostic factor as strong as infection. Beger *et al.*[3] noticed that infection was favoured by the extent of necrosis, as has been recently demonstrated in experimental pancreatitis in a rodent model of graded severity[25]. Finally, it is noteworthy that antibiotic prophylaxis of infection of necrosis, provided either by intravenous broad spectrum antibiotics[26] or by selective intestinal decontamination[27] effectively reduced infection rates in large controlled studies, but did not reduce mortality. Infection may therefore be indirect evidence for extensive necrosis, which would be the main independent prognostic factor.

As no case of infected necrosis cured by antibiotics and supportive therapy has been reported, percutaneous aspiration of the collections seen at CT is justified, a septic aspirate indicating the need for surgical drainage. When the first percutaneous aspiration performed for severe necrotizing pancreatitis is sterile, the subsequent course is not necessarily favourable. Patients with sterile necrosis may recover with supportive treatment, but one-half of the patients suffer secondary infection of necrosis, this being favoured by percutaneous drainage which should be therefore avoided. Repeated percutaneous aspirations should be performed if the condition of the patient deteriorates. Surgical necrosectomy and drainage appeared to be ultimately frequently required because of bioclinical deterioration, even if infection of necrosis was not demonstrated by repeated percutaneous aspiration.

Co-existing biliary anomalies and anatomical variants in choledochal cyst

T. TODANI, Y. WATANABE, A. TOKI, K. OGURA and Z.-Q. WANG

Department of Paediatric Surgery, Kagawa Medical University, 1750-1 Miki, Kitagun, Kagawa 761-0701, Japan

Background Excision is the treatment of choice for choledochal cyst, and free bile drainage is essential to avoid ascending cholangitis. However, anastomosis between the relatively narrow common hepatic duct and bowel (conventional anastomosis) in case of type IV-A cyst, co-existing biliary anomalies and anatomical variations may cause ascending cholangitis resulting from insufficient biliary decompression.

Methods One hundred and four patients with choledochal cyst were treated by cyst excision. Conventional anastomosis was performed in 22 patients and hilar anastomosis in 82.

Results An anastomotic stricture developed in nine of the 22 conventional anastomosis cases and all required reoperation. Of the 82 hilar anastomosis cases, only one required reoperation for a primary stricture. Co-existing biliary anomalies and anatomical variants were seen in 26 patients: (1) primary stricture in 18; (2) aberrant posterior duct in two; (3) low confluence of the hepatic ducts in two; (4) aberrant hepatic artery in two; and (5) very small bile duct in two. All 26 patients underwent widening of the ductal lumen (ductoplasty) or additional procedures.

Conclusion Complete removal of the extrahepatic bile duct and a wide hilar anastomosis is essential to prevent ascending cholangitis. Ductoplasty or additional procedure can be performed only at the hilum.

Excision has long been the treatment of choice for choledochal cyst with pancreatobiliary malunion[1]. Although Roux-en-Y hepaticojejunostomy distal to the hilum has been employed widely and conventionally for the subsequent biliary–enteric anastomosis, it does not protect against recurrent cholangitis if anastomotic or primary intrahepatic ductal strictures are present[2]. Free bile drainage is essential to avoid ascending cholangitis and can be obtained by a wide anastomosis at the hepatic hilum[3,4]. Anastomosis between the common hepatic duct and bowel (conventional anastomosis) performed in a type IV-A cyst often produces a relatively small anastomosis, as compared with intrahepatic ductal dilatation, and may result in insufficient biliary decompression[4]. In addition, co-existing biliary anomalies or anatomical variations are observed occasionally around the hepatic hilum[5,6] and require additional procedures to ensure free bile drainage in biliary reconstruction. The purpose of this paper is to advocate hilar hepaticoenterostomy for preventing ascending cholangitis and to describe surgical correction of these anomalies and variations.

Patients and methods

Between March 1969 and March 1997, 104 patients with choledochal cyst were treated by excision (cyst removal and biliary reconstruction) (*Fig. 1*). The first 22 patients before 1976 underwent a hepaticoenterostomy distal to the hilum (conventional anastomosis), nine of whom required reoperation for ascending cholangitis resulting from anastomotic stricture which developed several years after initial surgery. The nine patients presented either with a type I cyst (three patients) or type IV-A cyst (six), and underwent duodenostomy (four) or Roux-en-Y jejunostomy (five)[4].

In 1976, reoperation was required for anastomotic stricture in a young female patient who had undergone cyst excision and conventional anastomosis 7 years previously[2], and the choice of conventional procedure was re-evaluated. Subsequently, the 82 patients since 1976 have undergone hepaticoenterostomy at the hepatic hilum to provide a wider stoma, regardless of intrahepatic involvement[7].

Additionally, associated biliary malformations including primary ductal stricture and anatomical variations, which were corrected by some additional procedure at the time of biliary reconstruction, have also been recorded.

Paper accepted 20 October 1997

Results

There were no operative deaths. All patients were asymptomatic except for the nine with anastomotic stricture after conventional anastomosis[4] and one with primary simple ductal stricture described below. Of 104 patients, 55 (52·9 per cent) presented with a type IV-A cyst with an intrahepatic component, and 26 (25·0 per cent) had co-existing biliary anomalies and anatomical variations (*Table 1*; *Fig. 2*).

Primary ductal stricture

Primary ductal stricture was observed in 18 (32·8 per cent) of 55 patients with type IV-A cyst, mainly in the hilum, confluence or umbilical ducts (*Table 1*). These were divided into simple strictures and membranous strictures resembling septal duodenal stenosis in shape. Widening of the ductal lumen (ductoplasty), or some additional procedure, was performed for free bile drainage in all strictures (*Fig. 2*).

Simple stricture. This was observed at the hilum or confluence duct of 16 patients and was successfully repaired by ductoplasty at the hilum in all but one. The exception was a 17-year-old female patient who underwent cyst excision and end-to-end hilar anastomosis with Roux-en-Y jejunum[4]. A cholangiogram taken at initial surgery indicated a slight stricture of the left hepatic duct near the hilum, but the stricture was ignored. At the age of 32 years, 15 years after surgery, she suffered from epigastric pain, fever and jaundice. Percutaneous transhepatic cholangiography (PTC) confirmed intrahepatic gallstones with a moderate stricture of the left hilar duct which was accelerated by the incomplete hilar ductoplasty. Reoperation revealed no anastomotic stricture but atrophy of the lateral left hepatic segment. Lateral segmentectomy only was performed with a favourable outcome.

Fig. 2 Co-existing biliary anomalies and anatomical variants in choledochal cyst (left) and corrective procedures (right). Dotted lines indicate incision line

Membranous stricture. This was seen at the umbilicus in two patients. In a 9-year-old girl an operative cholangiogram revealed choledochal cyst with umbilical ductal stricture (*Fig. 3*). Dissection from the hilum to the umbilicus disclosed a membranous stricture, similar to a septal duodenal stricture in shape, and a long bilioduodenostomy was successfully performed after excision of the membrane. Computed tomography (CT) taken 3 months after operation showed that cystic dilatation at the umbilicus was reduced in size. The girl is now 15 years old and in good health.

Aberrant posterior hepatic duct

An aberrant posterior hepatic duct draining into the distal common hepatic duct was observed in a child aged 2 years[8] (*Fig. 2*). The aberrant duct was excised and joined to the hepatic duct at the hilum, after which hilar hepaticoduodenostomy was performed with a large stoma created by incisions extending along the lateral wall of both the hepatic and aberrant ducts.

Low confluence of the right and left hepatic ducts

Low confluence was observed in two patients where hepatic ducts joined at the low hilar level (*Fig. 2*). Hilar anastomosis was performed after cutting off both the

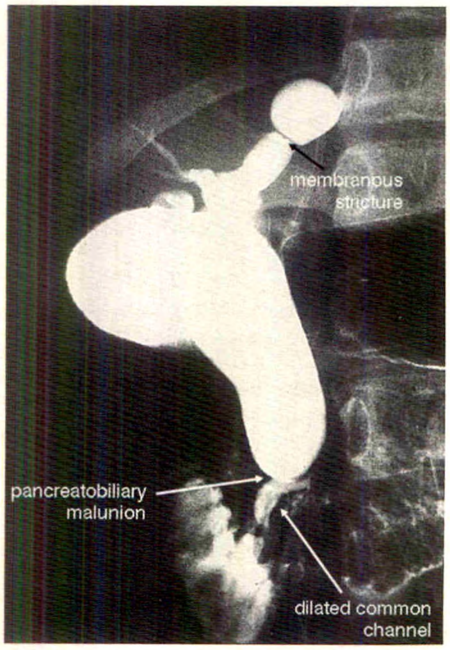

Fig. 3 Cholangiogram in a girl aged 9 years showing a membranous stricture at the umbilical portion. A long cholangioduodenostomy was performed after removal of the membrane

hepatic ducts, joining them at the hilum and making incisions in the lateral walls to create a large stoma.

Aberrant hepatic artery

The aberrant hepatic artery running in front of the common hepatic duct was observed in two children. It was easily replaced behind the jejunal loop as in normal anatomy at the time of biliary reconstruction (*Fig. 2*).

Very small bile duct

In two infants with type I cysts, the hilar and intrahepatic ducts were too small to perform a mucosal anastomosis between the duct and intestine[9]. After excision of the common hepatic duct at the hilum, the lateral walls of the hilar duct were incised to create a large stoma. The ductal mucosa was then everted and fixed to the liver parenchyma to prevent stricture formation. Finally, Kasai's procedure (hepatic portojejunostomy) was performed. Both children are now doing well 3 and 4 years after surgery respectively.

Discussion

Type IV-A cysts with intrahepatic involvement are often accompanied by a relatively narrow common hepatic duct smaller than the size of the intrahepatic ductal dilatation. Consequently, anastomosis between the common hepatic duct and bowel (conventional hepaticoenterostomy below the hilum) often produces a relatively narrow anastomosis which may lead to inadequate bile drainage from the liver and may aggravate anastomotic stricture with intrahepatic gallstones. Anastomotic strictures interfere with free bile drainage and cause bile stasis resulting in recurrent cholangitis. Reoperation for such instances is usually necessary 5 or more years after the initial surgery[4]. Removal of intrahepatic gallstones with a percutaneous transhepatic cholangioscope necessitates lengthy hospital stay and often results in unsatisfactory outcomes[4]. Early reoperation is necessary to improve the quality of life with short hospitalization when an anastomotic stricture with intrahepatic stones has been verified. Intrahepatic dilatation often regresses following adequate biliary decompression. Accordingly, a large hepaticoenterostomy across the bifurcation after complete removal of the extrahepatic bile duct should be performed primarily to prevent ascending cholangitis.

Type IV-A cyst also occasionally involves a primary ductal stricture which is detected by appropriate cholangiography, direct observation or intraoperative endoscopy[10]. Primary ductal stricture probably leads to intrahepatic ductal dilatation and gallstones[5,6,11,12], and may be classified into simple and membranous strictures[13]. Simple strictures are usually found in the intrahepatic duct near the hilum and are easily corrected by hilar ductoplasty and large hepaticoenterostomy[4,7]. However, it is occasionally overlooked because of an unsatisfactory cholangiogram and may become more severe as inflammatory attacks develop more frequently.

Membranous stricture tends to be found at the umbilicus. This can be excised by ductal dissection from the hilum to the umbilicus, following which a long cholangioenterostomy incorporating a hilar anastomosis obtains free bile drainage from the liver[5,13,14] (*Fig. 2*). When the left hepatic lobe is diseased, lateral segmentectomy is feasible[15]. Moreover, stricture of the upper duct rather than the umbilicus may require selective hepatectomy to eliminate the complicated lobe or repeated bouginage.

Complete removal of the extrahepatic and intrapancreatic bile ducts, and a wide hilar hepaticoenterostomy after ductoplasty around the hilum, or occasionally to the umbilicus, are essential procedures at primary surgery for choledochal cyst. Careful life-long follow-up should also be a routine part of the treatment, regardless of intrahepatic involvement. Given a wide anastomosis, favourable results can be expected in both the duodenostomy and jejunostomy groups[2,4] (*Fig. 1*).

Normal anatomical variants of the biliary tree or other anomalies in choledochal cyst are detected occasionally by cholangiography or direct vision at the time of surgery and frequently necessitate some procedure for their correction. An aberrant posterior hepatic duct draining into the distal common hepatic duct, however, seems to be rare[8]. The aberrant duct is excised and joined with the hilar hepatic duct, and hilar hepaticoenterostomy is performed with a large stoma. If the aberrant duct were ligated the posterior segment of the right lobe may develop biliary infection and result in subsequent atrophy.

In the low confluence of the right and left hepatic ducts, the anastomotic site around the confluence receives less blood supply than that in the hepatic hilum and may result in stricture. Accordingly, both hepatic ducts are excised at the hilum, anastomosed, and then both lateral walls are incised to provide a wide anastomotic stoma.

The aberrant hepatic artery running in front of the common hepatic duct is easily displaced behind the jejunal loop as in normal anatomy.

In some infants with choledochal cyst, hilar and intrahepatic ducts are too small to perform mucosal anastomosis between the duct and the intestine[9]. Anastomosis using a cuff of cyst to obtain sufficient stomal size is possibly unsuitable because it leaves the epithelium prone to stricture or cancer. After excision of the common hepatic duct at the hilum, incisions are performed in both hepatic ductal walls, after which the ductal mucosa is everted and fixed to the liver parenchyma to prevent stricture formation. Finally, Kasai's hepatic portojejunostomy remains the treatment of choice.

Randomized trial of early *versus* delayed laparoscopic cholecystectomy for acute cholecystitis

P. B. S. LAI, K. H. KWONG, K. L. LEUNG, S. P. Y. KWOK, A. C. W. CHAN, S. C. S. CHUNG and W. Y. LAU

Department of Surgery, Prince of Wales Hospital, Chinese University of Hong Kong, Shatin, New Territories, Hong Kong
Correspondence to: Professor W. Y. Lau

Background The aim of this prospective randomized study was to define the optimum management between early and delayed laparoscopic cholecystectomy for patients with acute cholecystitis.

Methods Patients were randomized to receive either early laparoscopic cholecystectomy within 24 h of randomization or initial conservative treatment followed by delayed laparoscopic cholecystectomy 6–8 weeks later.

Results There were 53 patients in the early group and 51 in the delayed group. There was no significant difference in conversion rate (early 21 per cent *versus* delayed 24 per cent), postoperative analgesic requirement (1 *versus* 2 doses) and postoperative complications. However, the early group had significantly longer operating time (122·8 *versus* 106·6 min, $P = 0{\cdot}04$) and shorter total hospital stay (7·6 *versus* 11·6 days, $P < 0{\cdot}001$).

Conclusion Early laparoscopic cholecystectomy is safe and feasible for acute cholecystitis with the additional benefit of shorter total hospital stay. Apart from a shorter operating time, treating patients with delayed laparoscopic cholecystectomy does not offer additional benefit.

Laparoscopic cholecystectomy has become the 'gold standard' for the treatment of symptomatic gallstones and chronic cholecystitis. However, there are still controversies over the use of laparoscopic cholecystectomy to treat acute cholecystitis. In the developmental stage of laparoscopic cholecystectomy it was considered 'unsafe' or 'technically difficult' to perform laparoscopic cholecystectomy for acute cholecystitis[1,2]. With increasing experience in laparoscopic surgery, a number of centres have reported on the use of laparoscopic cholecystectomy for acute cholecystitis, suggesting that it is technically feasible but at the expense of a high conversion rate, which can be up to 35 per cent[3–5].

Several randomized studies in the early 1980s had shown that performing early open cholecystectomy for acute cholecystitis was better than delayed cholecystectomy in terms of shorter hospital stay but both had similar operative morbidity and mortality rates[6,7]. Early surgery had since gained in popularity in the late 1980s[8].

In this laparoscopic era, the optimal time to carry out laparoscopic cholecystectomy for acute cholecystitis remains controversial and there are no prospective data to settle this issue. Successful laparoscopic cholecystectomy during the period of acute inflammation is associated with an earlier recovery and shorter hospital stay when compared with open cholecystectomy[9]. The potential advantages of early laparoscopic cholecystectomy can, however, be offset by a high conversion rate to open surgery. On the other hand, initial conservative treatment may lead to a technically easier delayed laparoscopic cholecystectomy after the acute inflammation has subsided, thus leading to a lower conversion rate. A prospective randomized study was performed to compare early and delayed laparoscopic cholecystectomy in the treatment of acute cholecystitis.

Paper accepted 29 October 1997

Patients and methods

Patient selection and study design

Approval for the study was obtained from the hospital ethics committee. From January 1993 to December 1995 all patients with a diagnosis of acute cholecystitis admitted to the surgical department at the Prince of Wales Hospital, Hong Kong, were considered eligible for the study. The diagnosis of acute cholecystitis was based on a combination of a compatible clinical picture (acute right upper quadrant tenderness, temperature greater than 37·5°C and white blood cell count greater than 10×10^9/l) and ultrasonographic evidence of acute cholecystitis (presence of gallstones in a thickened and oedematous gallbladder, positive sonographic Murphy sign and pericholecystic fluid collections)[10]. Patients were excluded from randomization if they: (1) had symptoms present for more than 1 week; (2) had had previous upper abdominal surgery; (3) had significant medical diseases that rendered them unfit for laparoscopic surgery; or (4) had coexisting common bile duct stones with ductal dilatation, acute cholangitis or acute pancreatitis. Informed consent was obtained. Patients were then randomized into either the 'early' group or the 'delayed' group according to a computer-generated randomization list kept by a third party.

In the early group laparoscopic cholecystectomy was performed within 24 h of randomization whereas in the delayed group conservative treatment with intravenous fluid and antibiotics including ampicillin, cefuroxime and metronidazole was given. Patients who responded to conservative treatment had elective laparoscopic cholecystectomy 6–8 weeks after the acute episode had subsided. On the second admission patients were routinely admitted 1 day before the scheduled operation. Patients who failed conservative treatment with worsening clinical signs or those who developed a recurrent attack of acute cholecystitis before the scheduled delayed cholecystectomy were treated with emergency laparoscopic cholecystectomy.

Quality assurance and the surgical procedure

Laparoscopic cholecystectomy, whether early or delayed, was performed by a group of eight experienced laparoscopic surgeons who each had performed more than 50 cases. The surgical procedure was similar to that described previously[4]. Pneumoperitoneum was created by the open technique. Dissection with electrocautery was used. The cystic duct was secured with polydioxanone clips and the cystic artery with titanium clips. Operative cholangiography was not performed routinely. Closed suction drains were inserted through the subcostal port to drain the subhepatic space at the end of the procedure. Resected gallbladders were sent for pathological examination. Intramuscular pethidine at a dose of 1 mg/kg every 4 h was offered on demand after operation.

Study parameters

Data were collected prospectively and included patient demographics, operative findings, conversion to open cholecystectomy and the reason for conversion, operating time, postoperative analgesic requirement, length of postoperative stay and total hospital stay (including the admission on presentation and admission for subsequent delayed surgery in the delayed group), and postoperative complications.

Sample size calculations and statistical analysis

In the authors' department the historical conversion rate for early laparoscopic cholecystectomy for acute cholecystitis was about 25 per cent. Based on the objective of detecting a 20 per cent reduction in the conversion rate in the delayed cholecystectomy group, sample size calculation revealed that for $\alpha = 0{\cdot}05$ (one-tailed) and statistical power = 0·8, at least 48 patients were needed in each group. Statistical analysis was performed with the *t* test, Mann–Whitney *U* test and χ^2 test as appropriate. $P < 0{\cdot}05$ was considered statistically significant.

Results

During the study period 31 patients were excluded before randomization and 104 were randomized (*Fig. 1*). Of the 53 patients randomized to the early group, 23 were men; mean(s.d.) age was 55·8(14·6) (range 25–78) years. In the delayed group there were 15 men; mean(s.d.) age was 56·1(14·4) (range 31–81) years. There was no significant difference between the sex ratio ($P = 0{\cdot}20$, χ^2 test) and the age of the patients in both groups ($P = 0{\cdot}90$, *t* test).

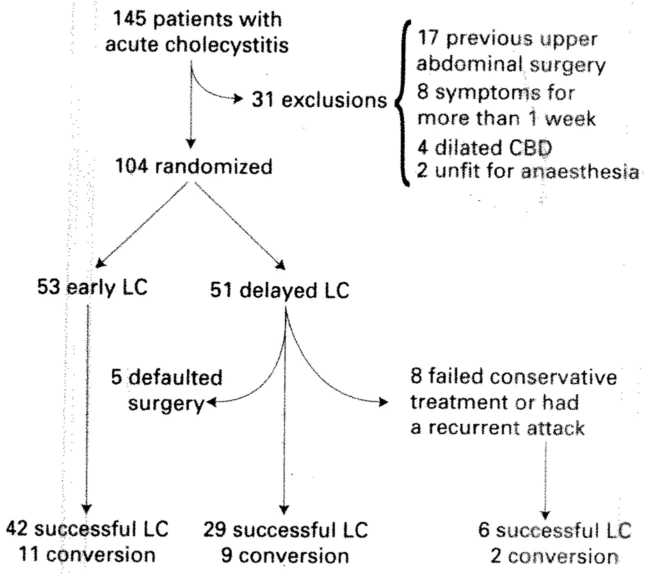

Fig. 1 Management scheme for the 145 patients with acute cholecystitis in the study. CBD, common bile duct; LC, laparoscopic cholecystectomy

Outcome

In the delayed group five patients defaulted surgery after successful conservative treatment. Emergency laparoscopic cholecystectomy was performed because of failed conservative treatment in seven patients and a recurrent attack of acute cholecystitis before the scheduled delayed cholecystectomy in one patient. Among these eight patients who had emergency laparoscopic cholecystectomy, there were two conversions to open surgery. No complication was noted in this group of patients.

Conversions to open surgery and operating time

Eleven (21 per cent) of the 53 patients in the early group and nine (24 per cent) of the 38 in the delayed group required conversion to open surgery ($P = 0{\cdot}74$, χ^2 test). The main reason for conversion in the delayed group was adhesions around Calot's triangle and the gallbladder, making dissection and identification of anatomical structures difficult. In the early group, additional inflammation or gangrenous changes of the gallbladder prevented successful dissection in some cases. Mean(s.d.) operating time in the early group was 122·8(36·0) (range 60–230) min and that in the delayed group was 106·6(37·3) (range 45–195) min ($P = 0{\cdot}04$, *t* test). If patients who had conversion were excluded, mean operating time in the early group was 118·8 min compared with 96·9 min in the delayed group ($P = 0{\cdot}02$, *t* test).

Postoperative complications

There was no major bile duct injury or death. The overall complication rate in the early group was 9 per cent (five of 53 patients) and in the delayed group 8 per cent (three of 38 patients) ($P = 0{\cdot}80$, χ^2 test). In the early group three patients developed subphrenic collections, two of which required ultrasonographically guided percutaneous aspiration. The other patient responded to conservative treatment with antibiotics. One patient had undetected common bile duct stones at operation and developed bile leakage from the cystic duct stump. He was treated with percutaneous drainage of the collection and common bile duct stone extraction by endoscopic retrograde cholangiopancreatography. One other patient developed a minor wound infection. In the delayed group one patient developed a subphrenic collection which required percutaneous aspiration, one had a minor wound infection and another postoperative respiratory failure which required mechanical ventilation for 3 days.

Postoperative analgesic requirement

Median postoperative analgesic requirement in the early group was 2 (range 0–17) doses of pethidine and in the delayed group 1 (range 0–7) dose ($P = 0{\cdot}14$, Mann–Whitney *U* test).

Pathological examination of resected gallbladders

In the early group all 53 resected gallbladders showed histological features of acute cholecystitis, and three had signs of gangrenous cholecystitis. In the delayed group all gallbladders showed features of chronic cholecystitis.

Total length of hospital stay

Mean(s.d.) total hospital stay in the early group was 7·6(3·6) (range 4–21) days and in the delayed group 11·6(3·4) (range 5–24) days ($P < 0·001$, *t* test). However, mean(s.d.) postoperative hospital stay in the early group was 4·8(3·1) (range 2–17) days and in the delayed group 3·0(1·9) (range 1–10) days ($P < 0·001$, *t* test). Mean(s.d.) preoperative hospital stay in the early group was 1·7(1·0) (range 0–3) days and in the delayed group 1·3(0·5) (range 1–2) days.

Discussion

In the early years of laparoscopic surgery acute cholecystitis was regarded as a relative contraindication to laparoscopic cholecystectomy[1,2]. It is only recently that laparoscopic cholecystectomy has been shown to be a feasible and safe procedure for acute cholecystitis[11,12]. The rate of conversion to open surgery in acute cholecystitis was reported to range from 6 to 35 per cent[3,11,13,14], which was higher than that for symptomatic gallstones. This reflects the increased technical difficulties in laparoscopic surgery for the acutely inflamed gallbladder. However, a high conversion rate to open surgery obviates the advantages of laparoscopic cholecystectomy. It can, therefore, be argued that, if 'delayed' laparoscopic cholecystectomy leads to a technically easier laparoscopic surgery with a resultant lower conversion rate[15], it may be a better treatment option for acute cholecystitis.

Such an assumption that initial conservative treatment will increase the chance of successful laparoscopic cholecystectomy at a later date and possible better outcome cannot be substantiated by this study. The delayed group had a slightly higher rate of conversion to open surgery, although the difference was not significant (21 per cent in the early group *versus* 24 per cent in the delayed group). In fact, the increase in dense adhesions around the gallbladder and porta hepatis after initial conservative treatment makes the laparoscopic dissection more difficult in a proportion of patients[12,14,15] and constitutes the main reason for conversion to open surgery. Eight patients (16 per cent) randomized to the delayed group failed conservative treatment or developed a recurrent attack of acute cholecystitis requiring emergency laparoscopic cholecystectomy, a value in good agreement with other studies[7,16].

The more frequent requirement to adopt technical modifications such as needle aspiration of the gallbladder, insertion of extra retraction ports or the use of plastic bags for gallbladder extraction to avoid contamination may well explain the longer operating time required in the early group. Postoperative complications and postoperative analgesic requirements were similar in both groups. The absence of major complications such as bile duct injury suggests that laparoscopic cholecystectomy can be performed safely in both early or delayed settings. Although the postoperative stay was longer in the early group, the total hospital stay (counting both admissions) was longer in the delayed group.

It is a general impression that there exists a range of different gallbladders from minimally inflamed to grossly thickened oedematous or even gangrenous cholecystitis with increasing technical difficulties. The diagnostic criteria for acute cholecystitis used in this study combined clinical and radiological diagnoses. As evidenced by histopathological examination of the gallbladders, the accuracy of the diagnosis of acute cholecystitis was 100 per cent in the early group. This confirmed that the patients did have acute cholecystitis and not simply biliary colic. However, under the exclusion criteria of the present study, some patients with severe acute or gangrenous cholecystitis who presented with symptoms of more than 1 week in duration might have been excluded. Although it has been shown that these patients have a very high conversion rate if early laparoscopic cholecystectomy is attempted[3], they constituted only 6 per cent of patients (eight of 145) in this study. Therefore, the effects of excluding these patients from the study would not be substantial.

In conclusion, both early and delayed laparoscopic cholecystectomy are feasible and safe in the treatment of acute cholecystitis. However, delayed laparoscopic cholecystectomy is not associated with a lower conversion rate. Like open cholecystectomy, early laparoscopic cholecystectomy offers definitive treatment during the same admission and avoids the problems of failed conservative treatment and delayed surgery. Furthermore, a reduction of total hospital stay is a major economic benefit to the current healthcare system.

Acknowledgements

The authors thank members of the general surgical teams in the Department of Surgery, Prince of Wales Hospital, in particular Drs C.C. Chung and C.K. Leow for support throughout the study period and in preparation of the manuscript.

Background Duplex ultrasonography is used increasingly to select patients for carotid endarterectomy. This study aims to clarify whether arteriography is still required.

Methods A total of 272 patients in whom duplex imaging indicated significant disease of the internal carotid artery underwent arteriography and the results were compared. Regarding the arteriogram as the 'gold standard', three aspects were considered: the accuracy of duplex ultrasonography in detecting significant stenosis, the ability of duplex imaging to identify patients who should have arteriography and whether the arteriogram provided important additional information that might influence a decision to operate.

Results Three patients (1 per cent) suffered a permanent neurological deficit as a result of arteriography. Of the 272 patients with significant stenosis identified by duplex ultrasonography, 241 (89 per cent) were confirmed as significant on arteriography. Duplex imaging was not able to predict accurately which arteriograms would provide useful additional information (sensitivity 59 per cent, specificity 65 per cent), whereas 89 arteriograms (33 per cent) contained information that might have influenced subsequent management.

Conclusion Duplex imaging is unable to detail the anatomy or determine the extent of carotid disease and may therefore lead to an inappropriate decision to perform carotid endarterectomy. Duplex imaging alone is not adequate before carotid endarterectomy.

Over the past decade there has been a gradual evolution in the preoperative assessment of patients for carotid endarterectomy towards less invasive investigation. This trend has resulted from the recognition of the significant risks associated with arteriography[1-9] and the increasing accuracy of modern duplex imaging. In the past, patients with symptoms attributable to carotid artery disease were initially investigated with duplex imaging and in those with evidence of significant stenosis of the internal carotid artery arteriography was performed to confirm the extent of disease. Since publication of the two multicentre trials, the North American Symptomatic Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST), which proved the efficacy of carotid endarterectomy, several studies[10-14] have attempted to develop duplex imaging criteria that correlate with the grading of arteriographic stenosis. Consequently many surgeons now regard carotid arteriography as unnecessary before surgery.

While the degree of carotid stenosis is clearly vital in determining treatment, other factors such as the extent of proximal or distal disease are equally relevant; in this respect, arteriography has advantages. The relative positions of anatomical structures (e.g. internal carotid artery and mandible) that arteriography readily demonstrates are also important in decision making. This study compares carotid arteriography with duplex imaging and considers whether duplex imaging alone provides sufficient information to determine whether carotid endarterectomy should be performed.

Patients and methods

Between January 1992 and May 1995, 285 consecutive patients (153 men and 132 women of mean age 67 years) with duplex scans indicating significant disease of the internal carotid artery underwent arteriography. These patients gave a history consistent with disease affecting the relevant carotid artery territory (e.g. previous stroke, amaurosis fugax, transient ischaemic attack). The study commenced with the introduction of a new colour duplex scanner (Acuson 128; Acuson, Uxbridge, UK) and concluded just before the introduction of digital subtraction arteriography as the standard technique for performing carotid arteriography. Throughout the 40-month study the imaging apparatus remained the same.

Duplex imaging was performed by one of two experienced vascular technicians before arteriography. Criteria for stenosis were based on velocity and waveform analysis, and haemodynamically significant stenoses were taken to be those with a doubling of the velocity at the carotid bifurcation with associated broadening of waveform on spectral analysis. The proximal common carotid and the proximal segment of the external carotid artery were both scanned routinely.

All patients in the study had both carotid arteriography and duplex imaging performed. The ability of sonographers to predict which patients required arteriography to clarify an abnormality identified on the scan was assessed prospectively. This applied to the last 86 patients in the study and the decision was based on the following criteria: (1) an atheromatous plaque was identified but its extent could not fully be ascertained, either because it was too high to image completely or because the plaque extended for more than 2 cm; (2) the stenosis was a significant distance from the carotid birfurcation; and (3) calcification of the plaque or vessel wall interfered with the ultrasound signal.

Carotid arteriography was carried out via the transfemoral or transbrachial approach with selective catheterization of the common carotid artery. It is policy of the unit to perform only lateral uniplanar views of the carotid vessels which also display the cerebral circulation. It is recognized that a uniplanar view

Paper accepted 24 November 1997

will give less information than multiplanar views but the requirement for two contrast injections in the latter case was thought to have the potential to increase complication rates.

Assessment of the arteriograms was made prospectively (without knowledge of the duplex result) by a vascular surgeon in conjunction with a sonographer from the vascular laboratory. The degree of stenosis of the internal carotid artery (based on the mean value of the two observers) was calculated by comparing the luminal diameter at the stenosis with that of the internal carotid artery distal to the lesion, consistent with the NASCET[13] method. Whilst the ECST[14] study reached similar conclusions to the NASCET at the stenosis greater than 70 per cent threshold, the method of stenosis measurement was different and it has been estimated that a 50 per cent stenosis from the NASCET study was equivalent to 70 per cent from the ECST[15]. Thus, for the purposes of this study any stenosis greater than 50 per cent on arteriography was regarded as significant.

If there was difficulty in measuring the stenosis accurately on the arteriogram (because of poor definition), the presence of this potential error was documented. Any additional information provided by the arteriogram which might alter the patient's management was recorded. The mean time lapse between duplex imaging and arteriography was 45 (median 41) days.

The number of patients having carotid endarterectomy and the complication rate were recorded to determine whether arteriography had influenced the decision to operate.

Results

No patient died as a consequence of arteriography, although two developed a persisting hemiparesis and a further patient had a visual field deficit following the procedure (1 per cent rate of persisting neurological deficit). Additionally two patients developed a groin haematoma.

Carotid arteriography and duplex imaging were performed on 285 patients; in 13 the arteriogram either failed or was not of sufficient quality to allow worthwhile comparison with the duplex scan. The accuracy of duplex imaging was therefore obtained by comparison with arteriography in 272 patients.

Duplex imaging correctly identified a significant stenosis in 241 patients (89 per cent). A similar analysis was performed after excluding all patients whose arteriograms were subject to observer error (i.e. accuracy in stenosis measurement could not be achieved). In this case, using 183 comparisons, duplex ultrasonography correctly identified a significant stenosis in 166 patients (91 per cent). Overall, useful information was obtained from the arteriograms in 89 (33 per cent) of the 272 comparisons performed (*Table 1*).

In 86 consecutive patients the sonographer was asked to indicate whether an arteriogram was advised based on information obtained from the scan. This opinion was then compared with the arteriogram result with respect to whether arteriography provided useful additional information. Duplex imaging had a sensitivity of 59 per cent and a specificity of 65 per cent with respect to evaluation of this selective arteriography policy.

Table 1 Additional information provided by arteriography in 89 patients

	No. of patients
Stenosis less than 50 per cent	25
High carotid birfurcation	23
Extensive distal atheroma	18
Very narrow internal carotid	10
Internal carotid occlusion	4
Tortuous internal carotid	5
Siphon disease	3
Proximal atheroma	1

Of the 272 comparisons, carotid endarterectomy was performed in 215 cases with an operative mortality rate of 1 per cent and an overall stroke rate of 8 per cent. In 26 patients surgery was not performed because of information obtained from the arteriogram.

Discussion

The need for preoperative arteriography before carotid endarterectomy was first challenged in 1982 when Blackshear and Connar[16] operated on four patients without arteriographic assessment. Since then a policy of selective arteriography has become widespread. It is now known that symptomatic patients with a 30–70 per cent carotid stenosis are equally well treated by medical therapy[17] or carotid endarterectomy, whereas those with stenosis of less than 30 per cent have a better outcome on medical therapy[14]. Finding a less invasive imaging technique than arteriography to distinguish between the group that will benefit from surgical rather than medical treatment is attractive, especially if it reduces overall morbidity. The risk of arteriography is significant (1 per cent had a persisting neurological deficit in this study, similar to other reports) and appears to be higher in patients with severe aortoiliac disease, renal insufficiency or documented allergy to the contrast medium. The risks in all patients with cerebrovascular disease are also increased[1]. The significant failure rate (5 per cent in this study), delays incurred waiting for the procedure and cost are notable disadvantages of arteriography.

By contrast, carotid duplex imaging is non-invasive, rapid and can be repeated on the same day as surgery. While arteriography has previously been regarded as the 'gold standard', and large multicentre trials proving the efficacy of endarterectomy have been based on it, duplex imaging may become the most appropriate test because it relies on dynamic flow disturbance rather than static images. Indeed, studies that have correlated arteriographic stenosis measurement with equivalent criteria for duplex imaging show great variation. Duplex imaging is operator dependent and each individual laboratory should audit its results carefully to ensure continuing quality.

Duplex imaging does have limitations: neither the aortic arch and proximal cranial branches nor the intracranial circulation, and in particular siphon disease, can be assessed. Proximal disease or contralateral occlusion can interfere with accurate classification of stenosis by affecting flow rates. The fact that these limitations are important in determining treatment is highlighted by this study in which 89 of the 272 arteriograms reviewed contained useful additional information and in 26 cases resulted in a change of management and a decision not to operate. Ideally, this group, which requires arteriography, could be identified by duplex scanning. Some have suggested a policy of selective arteriography but in this study, the sonographers were not able to select a group in which arteriography might demonstrate useful additional information, i.e. only 59% of those predicted by duplex imaging had extra information on arteriography.

Determining the severity of carotid stenosis is clearly crucial in decision making and, whilst duplex can achieve this[10–12], there is no evidence that patients who have endarterectomy after a duplex scan alone achieve a good long-term result compared with a control group. In this study, relying on duplex imaging alone would have resulted in an additional 31 patients having carotid endarterectomy.

No other imaging technique has allowed as accurate an assessment as duplex ultrasonography or arteriography, but magnetic resonance imaging may provide risk-free arteriography in the future, either alone or in combination with duplex imaging[18].

The results of this study demonstrate that duplex imaging is accurate in detecting haemodynamically significant stenosis but, in a proportion of cases, it fails to identify essential anatomical details and the extent of proximal or distal disease. Therefore, whilst it is suitable for screening, duplex imaging alone cannot determine whether surgery should be performed. By comparison, arteriography provides complete information and therefore should be performed in all patients before carotid endarterectomy.

Background Patients with symptomatic internal carotid artery (ICA) stenosis greater than 70 per cent in association with a contralateral ICA occlusion may have an increased risk of stroke following carotid endarterectomy. Such patients might benefit from the theoretically shorter ischaemic time offered by carotid angioplasty and stenting.

Methods Nine patients who underwent carotid angioplasty and stenting were monitored using near-infrared spectroscopy, continuous jugular venous oximetry and transcranial Doppler ultrasonography to detect both haemodynamic ischaemia and embolic events.

Results Significant ischaemia occurred in four of the nine patients once the stenosis had been crossed by the guidewire (spectroscopy and oximetry). Inflation of the angioplasty balloon resulted in a brief period of ischaemia and showers of emboli in all patients (ultrasonography) and this persisted for more than 3 min after balloon deflation in three patients. One patient had a major disabling stroke due to ICA thrombosis.

Conclusion Angioplasty and stenting in these high-risk patients may not confer any advantage over conventional surgery in terms of both haemodynamic ischaemia and embolization.

Percutaneous transluminal angioplasty (PTA) and stenting are established in the treatment of peripheral[1], coronary[2] and renal[3] arteriosclerosis. Although the benefit of carotid endarterectomy for severe symptomatic carotid disease is now proven[4,5], PTA–stenting is being advocated as an alternative[6]. In particular it is suggested that carotid angioplasty offers both clinical and economic advantages, being less invasive, avoiding general anaesthesia and allowing shorter hospital admission[6]. While the results of small published series appear encouraging[7–9], there have been no controlled trials comparing the outcome with surgery.

A potential advantage of PTA is the shorter ischaemic time associated with angioplasty balloon inflation compared with surgery. Conversely PTA is associated with release of multiple emboli[10], the effect of which cannot be predicted.

Patients at risk from haemodynamic ischaemia during surgery are those with a severe internal carotid artery (ICA) stenosis and a contralateral ICA occlusion[11–13]. These patients might benefit from PTA–stenting. The present study used transcranial Doppler ultrasonography (TCD), near-infrared spectroscopy (NIRS) and continuous jugular venous oximetry to monitor a group of high-risk patients undergoing carotid PTA–stenting.

Patients and methods

After obtaining ethics committee approval, patients with an ultrasonographically detected symptomatic ICA stenosis greater than 70 per cent and occlusion of the contralateral ICA underwent selective transfemoral carotid angiography to confirm the severity of the carotid disease. In an 18-month interval nine patients gave informed consent to undergo PTA–stenting. Their demographic details, symptoms and disease severity are shown in *Tables 1* and *2*.

Angioplasty–stenting

All interventions were performed by a single neuroradiologist under a standard isoflourane-based general anaesthetic. General anaesthesia was used on the basis that the procedure might be prolonged during the early experience and to facilitate accurate stent placement during controlled apnoea. The angiography

Table 3 Middle cerebral artery velocity, jugular venous oxygen saturation and changes in the concentration of cytochrome oxidase measured from an arbitrary baseline of zero during carotid percutaneous transluminal angioplasty–stenting

	Baseline	Guidewire	Inflation	Hyperaemia	At end of surgery
MCAV (cm/s)	72 (34–84)	48 (25–72)	0 (0–48)	88 (52–133)	81 (34–133)
$[caa_3]$ (μ mol/l)	0	− 0·2 (− 2·7–0)	− 0·4 (− 2·0–0·1)	0 (− 1·0–0·2)	0·2 (− 2·8–0·5)
$SJvO_2$ (%)	70 (56–80)	68 (49–75)	64 (43–70)	69 (55–80)	75 (60–85)

MCAV, middle cerebral artery velocity; $[caa_3]$, concentration of cytochrome oxidase; $SJvO_2$, jugular venous oxygen saturation

catheter was positioned in the common carotid artery via one femoral artery while the guidewire and angioplasty balloon–stent were delivered via the other groin. Intra-arterial heparin (5000 units) was given after positioning the guidewire. The first patient underwent angioplasty alone, whereas an ICA stent was deployed in the remaining patients (Palmaz stent, Johnson and Johnson Interventional Systems, Warren, New Jersey, USA, $n = 2$; Strecker stent mounted on an Ultrathin angioplasty catheter, Meditech, Boston Scientific, Watertown, Massachusetts, USA, $n = 6$). All stents measured 20–40 × 5–6 mm and were deployed with a 15-s inflation. Further inflations were used to expand the stent fully if required. Intravenous heparin was given for 72 h after the procedure. Thromboprophylaxis was continued with self-administered enoxaparin, 20 mg daily for 6 weeks, and long-term enteric-coated aspirin (300 mg daily).

Monitoring

Transcranial Doppler ultrasonography. Ipsilateral middle cerebral artery velocity (MCAV) was measured with a transcranial Doppler ultrasonographic probe (EME Pioneer TC2020; Nicolet Instruments, Warwick, UK) positioned over the temporal window and held with a headstrap. This instrument includes emboli detection software (data saved for off-line analysis), and Spencer's criteria[14] were used to distinguish artefact from embolus. No attempt was made to differentiate between air and particulate emboli. MCAV measurements were also stored on computer disk.

Near-infrared spectroscopy. The Critikon Cerebral Redox Research Monitor 2001 (Johnson and Johnson, Ascot, UK) measures trends in the cerebral concentrations of oxyhaemoglobin $[HbO_2]$, deoxyhaemoglobin [HHb] and cytochrome oxidase $[caa_3]$. A decrease in $[HbO_2]$ with an increase in [HHb] indicates increased cerebral oxygen extraction (tissue ischaemia), while a decrease in $[caa_3]$ is believed to represent cellular ischaemia. The probe was attached to the forehead ipsilateral to the vessel for PTA–stenting.

Continuous jugular venous oximetry. Jugular bulb venous oxygen saturation ($SJvO_2$) was measured continuously with the Oximetrix III system (Abbott Instruments, Epsom, UK). After induction of general anaesthesia, one internal jugular vein was cannulated and the fibreoptic catheter was positioned with its tip in the jugular bulb. In six patients the dominant internal jugular vein, as judged by the angiogram, was used. In the remaining three patients, with equal venous drainage, the catheter was inserted on the side of the occluded ICA. During monitoring a fall in $SJvO_2$ reflected inadequate cerebral oxygen delivery.

Results

All interventions were technically successful with a reduction in median (range) stenosis from 80 (range 70–90) to 10 (0–30) per cent. However, one patient suffered a disabling stroke caused by acute thrombosis of the stented artery. One further patient, taking warfarin, developed a large retroperitoneal haematoma and another had a large groin haematoma. Neither required intervention. There were no other complications.

The patterns of change in MCAV, $SJvO_2$, $[HbO_2]$ and $[caa_3]$ were similar, with a fall on balloon inflation and reactive hyperaemia following angioplasty–stenting (*Table 3*). However, there were important variations: crossing the stenosis with the guidewire produced a significant reduction in MCAV, $SJvO_2$, $[HbO_2]$ and $[caa_3]$ in four of the nine patients and $[caa_3]$ remained depressed for more than 3 min after angioplasty–stenting in three of the patients, suggesting prolonged cellular ischaemia. Less importantly, balloon inflation resulted in a small, transient, increase in $SJvO_2$, $[HbO_2]$ and $[caa_3]$. This presumably reflected a brief augmentation in flow.

Emboli were detected in all patients during guidewire manipulation but most notably following balloon deflation. In addition, each bolus of contrast produced signals similar to showers of emboli. The median number of emboli was 128 (range 90–250) per patient and in one patient transcranial Doppler ultrasonographically detected emboli were associated with brief ischaemic episodes detected by both NIRS and jugular venous oximetry.

Two patients developed evidence of reperfusion hyperaemia following stent deployment with steadily rising MCAV, $SJvO_2$, $[HbO_2]$ and $[caa_3]$. This was controlled by lowering the blood pressure until MCAV reached preangioplasty levels, then allowing the pressure to rise slowly again. Acute ICA spasm was noted in two patients but resolved without complications.

In the patient who developed an acute ICA thrombosis, two stents were deployed, one across the carotid bifurcation and the other in the distal common carotid artery. The angioplasty balloon became ensnared on one of the stents and, while attempts were being made to detach it, a reduction in cerebral perfusion was detected by all monitoring modalities. An initial angiogram demonstrated ICA spasm but, following a further fall in MCAV, angiography confirmed acute thrombosis. Although lysis was achieved with locally delivered tissue plasminogen activator after 15 min, and MCAV, $SJvO_2$ and $[HbO_2]$ returned to normal, $[caa_3]$ remained depressed and the total ischaemic time exceeded 20 min. The patient developed a dense hemiplegia and computed tomography confirmed ipsilateral infarction in the distribution of both the middle cerebral artery and watershed areas.

Discussion

The advantages of carotid PTA–stenting over surgery are less clear than for renal, coronary and peripheral arterial PTA. Proponents argue that it avoids general anaesthesia and requires a shorter hospital stay[6]. However, the potential complications of carotid PTA–stenting include intraprocedural embolic events and an unknown incidence of recurrent stenosis. Furthermore, carotid endarterectomy can be performed under regional anaesthesia with hospital admission as short as 24 h[15]. Finally, while the two major multicentre trials of carotid endarterectomy reported combined stroke–death rates of 5·8 and 7·5 per cent, the outcome in specialist centres may be better[16,17].

In this study multiple emboli were detected during all procedures, particularly on balloon deflation, confirming the findings of Markus *et al.*[10]. These were at least ten times more frequent than observed during carotid endarterectomy. Emboli were also detected during guidewire manipulation, which emphasizes the importance of minimizing instrumentation across the stenosis. Furthermore this suggests that the double balloon technique of Theron *et al.*[18], in which an additional balloon is inflated distal to the angioplasty site to trap embolic material, will not prevent all embolic events. Henry and co-workers (personal communication) found no reduction in stroke rate using this approach.

The clinical significance of cerebral emboli remains unclear. In the present study one patient, who had no neurological complications, showed evidence of cerebral ischaemia on $SJvO_2$ and NIRS monitoring, apparently related to showers of emboli. In addition Gaunt *et al.*[16] have shown that multiple emboli during carotid surgery cause subtle neuropyschological deficits. In the present study $SJvO_2$[19] and NIRS measurements provided a detailed assessment of the influence of altered cerebral blood flow on tissue oxygenation. When blood flow is inadequate, cerebral oxygen extraction increases and $SJvO_2$ falls. These measurements are complemented by NIRS which, although regarded as experimental, provides a direct measure of tissue oxygenation ($[HbO_2]$) and cellular ischaemia ($[caa_3]$)[20]. That the changes in $[HbO_2]$ and $SJvO_2$ were similar supports the validity of NIRS. Interestingly the $SJvO_2$ changes occurred several seconds later, reflecting the time taken for blood to travel from the cerebral hemisphere to the jugular bulb.

The changes in cerebral blood flow and oxygenation during PTA–stenting were similar to those following clamp application and release during carotid endarterectomy[21]. MCAV, $SJvO_2$, $[HbO_2]$ and $[caa_3]$ fell during balloon inflation, followed by transient hyperaemia on deflation. The initial overshoot in MCAV is likely to represent increased flow through a dilated vascular bed. Autoregulation takes several minutes to readjust. The parallel changes in the parameters of tissue oxygenation support this hypothesis.

Although PTA–stenting was used in these high-risk patients to reduce the duration of ischaemia, this did not always happen. In four patients MCAV fell following guidewire insertion resulting in prolonged ischaemic times of 8–22 min, longer than required for shunt insertion during carotid endarterectomy. Furthermore, cellular ischaemia (lower $[caa_3]$) persisted for more than 3 min in three patients after balloon deflation despite apparently adequate oxygen delivery (measured by $[HbO_2]$, $SJvO_2$, MCAV), suggesting a temporary uncoupling of oxygen utilization at a cellular level. Thus, in patients with multiple, severely diseased vessels, PTA–stenting may not deliver a shorter ischaemic time. Although a shunt can be inserted when ischaemia is detected during operation, there is no comparable strategy for PTA.

The present results may represent a learning process, but suggest that patients who have a high risk of embolic or haemodynamic ischaemia during surgery are also at risk during PTA–stenting. While PTA of other vessels often avoids the need for major surgery, if complications occur, or if PTA fails, remedial surgery is usually possible. Carotid PTA–stenting differs in this respect because surgery is unlikely to salvage any of the neurological complications of endovascular therapy.

Reservations have been voiced about the current enthusiasm for carotid PTA–stenting, including the view that the technique should be performed only within controlled trials[22]. Routine carotid PTA–stenting will be justified only if such trials confirm that both the early (stroke, death) and late (recurrent stenosis) results are as good as those for carotid endarterectomy.

Prospective randomized trial of woven *versus* collagen-impregnated knitted prosthetic Dacron grafts in aortoiliac surgery

J. W. QUARMBY, K. G. BURNAND, S. J. M. LOCKHART, A. E. DONALD, K. M. SOMMERVILLE, C. W. JAMIESON and N. L. BROWSE

Department of Surgery, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH, UK

Background Despite the theoretical advantages of coating knitted grafts with a material designed to reduce blood loss, their performance has not been directly compared with woven grafts in a prospective randomized trial. The aim of this study was to compare the graft handling qualities and operative blood loss of the two types of arterial prosthesis, as well as complication rate and patient survival at 1 year.

Methods A total of 267 consecutive patients having surgery for occlusive or aneurysmal disease of the aortoiliac arteries were randomized to receive woven (141 patients) or knitted collagen-impregnated Dacron (126 patients) grafts. Graft patency was assessed on discharge and at 1 year by duplex imaging.

Results Mean(s.d.) intraoperative blood loss was statistically greater with woven grafts (1690(1424) ml) compared with knitted (1363(1172) ml) ($P = 0{\cdot}049$). An insignificant 1-year increase in mean(s.d.) graft diameter of 1·2(0·2) mm was found at the distal anastomosis in the knitted group. There was no difference in graft patency between the groups and only one graft became infected.

Conclusion This study suggests that knitted and woven grafts have similar clinical performance and therefore the less expensive material (woven) should usually be selected unless haemorrhagic complications are anticipated.

Dacron (Du Pont, Wilmington, Delaware, USA) has been the material of choice for aortic prosthetic grafts since it was introduced in the late 1950s[1]. The original grafts were of woven construction which resulted in a small pore size and little bleeding through the graft. The development of industrial machine manufacturing led to the production of knitted grafts which, although much more porous, had the theoretical advantage of improved operative handling qualities. This was followed by the addition of a velour construction to increase tissue incorporation[2,3], and more recently by impregnation with collagen or gelatin, avoiding the necessity to 'preclot' the graft with the patient's own blood, thus reducing initial blood loss[4].

Dacron is a synthetic multifilament yarn which has to be either woven or knitted to form a sheet. Woven material, manufactured with warp and weft fibres, does not rely on looping of the yarn around a needle and the material is therefore more compact[4]. Weaving results in a low-porosity graft with greater strength and resistance to deformation compared with the looser structure of the knitted graft. The stiffness of the woven structure is thought to make it more difficult to handle and suture compared with the more elastic knitted structure. Knitted grafts behave like knitted garments which are prone to stretching, and the stability of Dacron is not as good as was originally thought[5].

Despite the theoretical advantages of coating knitted grafts with a material designed to reduce blood loss, their performance has not been directly compared with that of woven grafts in a prospective randomized trial.

The purpose of this study was to compare the graft handling qualities and operative blood loss of these two arterial prostheses. In addition, graft patency, infection rate, false aneurysm formation and patient survival at 1 year was assessed.

Paper accepted 3 September 1997

Patients and methods

All patients having elective surgery for an infrarenal aneurysm or occlusive aortoiliac disease between January 1991 and August 1994 were asked to participate in this study. After obtaining informed consent patients were prospectively and randomly allocated to one of two groups using Geigy randomization tables. A woven Dacron graft (Cooley Verisoft) was used for one group while the other had a presealed knitted Dacron graft inserted (Microvel double Velour with Haemashield). Both of these grafts were manufactured and supplied by Meadox (Caddington, UK).

All patients with occlusive disease had a bifurcated graft inserted, end to side, between the upper end of the infrarenal aorta and the iliac or common femoral arteries. Patients with aneurysmal disease had either a tube graft inlayed end to end, or a bifurcated graft stretched to the iliac or femoral arteries with an end-to-side distal anastomosis and closure of the common iliac vessels, the choice being dependent on the state of the iliac arteries.

The presence of diabetes mellitus, hypertension or hyperlipidaemia and smoking habits were recorded. The intraoperative blood loss was estimated from swab weighing and measurement of the volume of blood within the suction bottle. The time taken to perform the distal anastomosis was recorded.

The patients were reviewed 1 year later when graft patency, dilatation (increase in diameter) and the presence of any myointimal hyperplasia were assessed using duplex imaging (Acuson 128 XP10; Acuson, Mountain View, California, USA). The anastomoses were displayed longitudinally and callipers placed across both graft and native artery to measure the luminal diameter. These measurements were compared with the known graft diameter at the time of insertion. The ultrasonography technician did not know the type of graft that had been inserted. An intravenous digital subtraction arteriogram was obtained if the duplex study was equivocal or if there was any suggestion of graft occlusion.

A small group of 18 patients (16 knitted and two woven tube grafts) who had initially been recruited and randomized were subsequently withdrawn when it became apparent after operation that they would not return to the UK for follow-up. There is therefore a slight imbalance between the number of knitted and woven grafts included.

Results

A total of 267 patients were entered into the trial, of which 225 (84·3 per cent) were men and 42 (15·7 per cent) women. Some 141 patients (52·8 per cent) had woven and 126 (47·2 per cent) had knitted grafts inserted. Of the 141 woven grafts 86 (61·0 per cent) were bifurcation and 55 (39·0 per cent) were tube grafts. Of the 126 knitted grafts 88 (69·8 per cent) were bifurcation and 38 (30·2 per cent) were tube grafts. Some 115 patients (43·1 per cent) had aortoiliac occlusive disease and 152 patients (56·9 per cent) had an aortic aneurysm. Mean(s.d.) age of the patients with occlusive disease was 60·4(8·4) years and of those with aneurysms was 68·8(7·7) years. The patients with occlusive disease had a mean(s.d.) claudication distance at the time of surgery of 140(96) yards.

Actual blood loss was extremely variable and ranged from 150 to 10 000 ml, but the mean(s.d.) operative blood loss was significantly greater in patients who had a woven graft inserted (1690(1424) ml) compared with those with a knitted graft (1363(1172) ml) ($P = 0{\cdot}049$, Student's *t* test).

Mean(s.d.) time taken to construct the groin anastomosis in patients who had a woven bifurcation graft was 18·8(7·5) min and 18·0(7·5) min for a knitted graft.

Ten patients died in hospital (3·7 per cent), all within 24 h of surgery. Three (1·1 per cent) died as a result of technical problems, but none related to the grafts. Ten further patients (3·7 per cent) died within 1 month of discharge (30-day mortality rate of 7·5 per cent). Another 31 patients died in the next 11 months, giving an overall 1-year mortality rate of 19·1 per cent and a remaining 216 patients potentially available for follow-up. Of these 216 patients, 187 (86·6 per cent) were contacted and rescanned but 29 (13·4 per cent) could not be traced or recalled despite stringent efforts. The cause of death given on the death certificate was available for 21 of the 31 late deaths. Ten patients had died from myocardial infarction and five from heart failure. The cause of death was not related to atherosclerosis in the remaining six.

All grafts were patent at the time of discharge. A single limb of six bifurcated grafts (2·2 per cent of all grafts) had occluded by 1 year. Three of the occluded grafts were woven and three knitted. All had been inserted for occlusive disease. No tube graft occluded and no bifurcation graft developed bilateral occlusions.

There was a mean(s.d.) reduction in diameter of the woven grafts at 1 year of 1·26(1·75) mm compared with the diameter at discharge. There was a mean(s.d.) increase in the diameter of knitted grafts at 1 year of 1·2(0·2) mm indicating a small increase in the cross-sectional area. No evidence of myointimal hyperplasia was found at 1 year at any of the distal anastomoses.

One knitted graft became infected when a graft–enteric fistula developed. This patient died 6 months after the operation. No other graft infections had occurred by 1 year.

Discussion

Manufacturers' sales suggest that woven grafts are still more popular than knitted grafts (personal communication). Various modifications have been made in both types of graft which have been claimed to improve performance but until now the two types of graft have never been evaluated in a prospective randomized study.

Double velour knitted Dacron aortic grafts have been shown to have greater anastomotic strength than woven aortic grafts in models, but both were found to be less satisfactory than an equivalent polytetrafluoroethylene graft[6]. Biophysical, histopathological and ultrastructural studies in a few grafts removed after many years have shown that the fibre structure and resistance to degradation is better in woven than knitted Dacron grafts[7].

The interlacing structure of the woven graft with parallel fibres arranged compactly at right angles to each other is much more resistant to stress than the equivalent knitted graft where the looped structure is more prone to deformation[8]. It is thought that the repetitive pulsatile pressure of arterial blood is responsible for the dilatation found in knitted grafts causing the looping nature of the knit to take up a more elliptical shape[8]. The tighter the knit the greater the resistance to deformation[5]. Modern knitted grafts may not have the dilatation problems of their predecessors. In the few retrospective studies that have compared woven and knitted grafts dilatation is the most commonly reported long-term complication of knitted Dacron bifurcation grafts. Warp-knitted grafts do not unravel, curl up, or fray at the edges when cut, unlike woven grafts[8–11], but suture line disruption, anastomotic aneurysms, holes, tears, mural thrombus, embolization, bleeding and infections are all more common[8]. Many surgeons choose knitted grafts because of their better intraoperative handling qualities.

Recent improvements in woven grafts, including those used in this study, have eliminated unravelling and reduced the problems of fraying by using an interlocking stitch. Graft pliability has been increased by the use of three low-twist yarns and a loose crimp. Pseudointima fixation may be improved by the addition of an internal velour surface[12].

The condition of knitted and woven Dacron aortoiliac grafts has been assessed retrospectively using computed tomography[13]. Knitted grafts were found to dilate most in the first year with only marginally greater increases in diameter at 5 years. The mean dilatation of the main trunk of a knitted graft was 34 per cent after 5 years compared with 15 per cent for a woven graft. The limb dilatation was 42 per cent for the knitted compared with 25 per cent for the woven. Some 9 per cent of the knitted grafts developed a proximal anastomotic dilatation compared with 2 per cent of the woven grafts[13].

In a small study recently performed in this unit it was found that grafts were all within 1 mm of manufactured size when assessed by duplex imaging immediately after insertion. Nothing like the amount of dilatation was found in the knitted grafts inserted in the present study after 1 year and this may reflect improved manufacturing technology. Woven grafts do not dilate and the present study demonstrated only a small reduction in diameter without any loss of patency.

There was no appreciable difference in the time taken to perform the groin anastomoses for either graft, which suggests that there is little difference in their handling properties. Only one patient developed a graft infection.

This very low infection rate makes a single-centre study to investigate the relative risk of graft infection in the two groups totally impracticable.

Collagen impregnation of a knitted graft reduces the intraoperative blood loss and avoids the time-consuming process of preclotting. The collagen-impregnated knitted grafts used in this study had a small but significant reduction in mean blood loss in comparison to their woven equivalents. The clinical benefits were small, saving approximately one unit of blood per patient. This advantage would have been negated had the woven graft been collagen impregnated. Such a graft is now available.

Myointimal hyperplasia develops at the anastomoses of both polytetrafluoroethylene and Dacron grafts and has hampered the development of small diameter prosthetic grafts by causing stenosis and occlusion[14]. Myointimal hyperplasia develops with equal frequency in woven and knitted Dacron grafts implanted as different limbs of composite aortobifurcation grafts in animal models[15]. Duplex imaging in the present study was unable to detect myointimal hyperplasia by 1 year in either type of graft.

Grafts inserted for aneurysmal disease are known to have a better patency than those inserted for stenosing disease[16]. Graft occlusions occur almost exclusively in single limbs of bifurcation grafts inserted for aortoiliac occlusions and often develop in the first 100 postoperative days[16]. Up to 12 per cent of graft limbs occlude by 5 years[8], and this may represent a low estimate of the true figure. A 15-year follow-up of patients who had aortobifemoral Dacron grafts inserted for occlusive disease showed that only 25 per cent of patients survived and only 20 per cent still had both graft limbs patent[17].

No overall difference in the patency of woven and knitted grafts was found in a small retrospective study of 79 patients[18]. In the present study six early unilateral graft limb occlusions were detected with three in each of the woven and knitted groups. This is too small a number to justify any comparison between the two graft types but an overall occlusion rate of 2·2 per cent at 1 year was lower than expected.

Patients having aortoiliac surgery have a reduced life expectancy. The mortality rate in this study of just under 20 per cent at 1 year is comparable to other reports[4,16,19]. The high mortality rate at 1 year combined with the low occlusion and infection rates have reduced the power of this study to detect minor differences in these complication rates and a large randomized multicentre study would be required to show a significant difference.

The results of the present study do not support the view that bifurcated prostheses made of knitted and impregnated Dacron have better patency or lower infection rates than their woven Dacron equivalents. As the intraoperative and postoperative performances are so similar it is more appropriate to consider the price of the two grafts. In the UK at present a non-impregnated woven prosthesis costs approximately half the price of the knitted alternative manufactured by the same company, and should therefore be the graft of first choice.

Background Brothers of patients with an abdominal aortic aneurysm (AAA) are at high risk. In the present study brothers of patients who underwent elective AAA surgery were invited for aneurysm screening and the psychological consequences studied.

Methods All brothers over the age of 50 years were invited for abdominal ultrasonography. They were asked to complete a standard psychological well-being questionnaire both before, and 3 months after screening.

Results Some 571 brothers were identified: 251 were dead, 35 lived abroad, 16 could not be contacted for other reasons, 46 refused to participate and 13 were already known to have an AAA. Some 210 subjects (37·8 per cent) accepted the offer of screening. A new AAA was detected in 26 (12·3 per cent, 95 per cent confidence interval 8–18 per cent) of the men screened resulting in an overall prevalence of 18 per cent (95 per cent confidence interval 13–26 per cent). Eight (3·8 per cent) aneurysms were 5 cm or more in diameter and elective surgery was performed in five patients (2·4 per cent). The psychological dimensions of well-being (depression, anxiety, energy, and positive well-being) had not changed significantly 3 months after screening.

Conclusion The prevalence of AAA in brothers of patients with AAA is far higher than in the overall male population of the same age. Screening does not seem to have a negative influence on psychological well-being.

The overall mortality rate following ruptured abdominal aortic aneurysm (AAA) is over 80 per cent[1]. The risk of death associated with elective aortic surgery is approximately 5 per cent[2,3]. Screening may be a way of reducing total mortality from ruptured AAA. Ultrasonographic imaging of the aorta is cheap, and sensitivity and specificity rates are estimated to exceed 95 per cent[4,5]. Aortic diameter can be measured within a detection range of less than 2·2 mm[6]. The estimated prevalence of AAA within a random sample of 65–74-year-old men is 3–6 per cent[7]. To increase the yield of a screening programme, identification of subgroups known to have a higher prevalence of AAA has been proposed[7,8]. Several studies have shown a clear familial aggregation of AAA. Prevalence rates of 19–29 per cent in brothers have been reported[9–14]. Several aspects of screening need to be studied before screening for AAA in brothers is introduced[15]. In a prospective multicentre study the yield of a targeted screening programme for brothers of patients who had elective AAA surgery was investigated and the psychological consequences of screening were studied.

Patients and methods

The study involved the brothers of 291 patients (261 men and 30 women) admitted to five hospitals in the Netherlands between 1 May 1993 and 1 May 1995 for elective infrarenal AAA surgery. In the district hospitals of St Antonius Hospital in Nieuwegein and the Westeinde Hospital in the Hague, 116 and 36 patients underwent aortic surgery respectively. In the University Hospitals of Utrecht, Maastricht, and Leyden, 68, 38, and 33 operations were performed respectively. Mean(s.d.) age of the patients was 69(8) (range 45–87) years. All patients were requested to supply age, vital status, and address of any brothers. Consent for contacting the brothers was also requested.

Brothers who were still alive and 50 years of age or older were contacted by telephone and provided with information regarding the study. They were invited for ultrasonography of the abdominal aorta in a hospital near their home. They were asked to complete general health and well-being questionnaires. In the general health questionnaire, information pertaining to the following items was registered: smoking habits, previous myocardial and cerebral infarction, use of antihypertensive drugs and diabetes mellitus. The well-being questionnaire was psychological in nature (translated into Dutch) aimed at assessing the influence of screening on the four dimensions of depression, anxiety, energy, and positive well-being. It contained six items for depression, six for anxiety, four for energy and six for positive well-being. Higher total and domain scores indicated better psychological well-being. The validity[1] and reproducibility of this self-reported questionnaire is good[16].

Three months after ultrasonography the participants were asked once again to complete the well-being questionnaire. Results of the ultrasonography were sent to the trial office by general practitioners. An AAA was defined as a localized aortic dilatation with an anteroposterior diameter of 30 mm or more, or 1·5 times the proximal aortic diameter[17]. Two measures were calculated: the new detection rate and the overall prevalence comprising newly detected AAAs and the AAAs already known. Differences between subgroups were tested using χ^2 test. Mean scores of well-being and the subdomains were compared using

Paper accepted 4 September 1997

the paired *t* test. The study was approved by the medical ethics committees of all participating centres.

Results

Collectively, the 291 patients who underwent elective AAA repair had 603 brothers. Of this total, 32 were under 50 years of age, 251 had died, and 16 could not be contacted because the original patient had not provided a recent address. Of the remaining 304 brothers, 269 were judged eligible for the study. Of these, 46 refused screening (generally because of health problems). Thirteen individuals were already known to have an AAA and were also not included in the study. Some of them had already had AAA repair. Some 210 brothers (79 per cent of those eligible) participated in the study and underwent abdominal ultrasonographic imaging.

An AAA was detected in 26 brothers. The new detection rate was 12·3 per cent (95 confidence interval (c.i.) 8–18 per cent) and the overall prevalence rate (26 plus the 13 AAA already known) was 18 per cent (95 per cent c.i. 13–23 per cent). Mean(s.d.) diameter of the aneurysms was 4·2(1·4) cm, the median was 3·4 cm (25th percentile 3·0 cm, 75th percentile 5·1 cm). In 15 men the AAA was smaller than 4 cm. In eight (3·8 per cent) the AAA was 5 cm or more. Five of these had aortic aneurysm repair. Seven men are included in a follow-up schedule, four died from other illnesses during follow-up. Follow-up was not considered necessary by the participating surgeons in the remaining ten men who were elderly, suffered from comorbidity and had a relatively small AAA.

Brothers with an AAA were older than brothers without an AAA (mean difference 3·5 years), and more commonly had a history of myocardial infarction ($P = 0{\cdot}04$), transient ischaemic attack or stroke ($P = 0{\cdot}09$) (*Table 1*). A total of 174 (83 per cent) of the participants in the study completed the well-being questionnaire before, as well as three months after the ultrasonographic scan (*Table 2*). There were no significant differences either in the total well-being sum-score ($P = 0{\cdot}8$) or in the scores of the different domains.

Table 1 Characteristics of brothers with and without abdominal aortic aneurysm

Characteristics	All brothers* ($n = 210$)	Brothers without AAA ($n = 180$)	Brothers with AAA ($n = 26$)
Age (years)			
50–59	60 (29)	55 (31)	4 (15)
60–69	96 (46)	83 (46)	12 (46)
70–79	47 (22)	37 (21)	8 (31)
80 +	7 (3)	5 (3)	2 (8)
Cardiac disease	64 (31)	54 (30)	9 (35)
Myocardial infarction	29 (14)	22 (12)	7 (27)
Angina	38 (18)	33 (18)	4 (15)

	Before screening	After screening
Total score for well-being	53(12·1)(0·9)	53·2(12·4)(0·9)
Subscales		
Depression	3·4(4·2)(0·3)	3·2(3·9)(0·3)
Anxiety	3·0(3·6)(0·3)	3·4(4·8)(0·4)
Positive well-being	14·2(4·2)(0·3)	14·4(4·6)(0·4)
Energy	9·2(2·9)(0·2)	9·4(3·1)(0·2)

Values are mean(s.d.)(s.e.m.)

Discussion

One-third (210 of 603) of the brothers initially identified were screened for an AAA. The mean age (69 years) of the index patients was relatively high and a significant number of their brothers had died. The prevalence of AAA in the study (18 per cent) was higher than in the overall male population of the same age (3–6 per cent)[7]. Prevalences of between 13 and 29 per cent have been reported in other studies[9,11–14]. Except in the case of one study, where no definition of AAA was provided, researchers applied size definitions similar to this study. The present study differed in that it was limited to brothers 50 years of age and older. The research conducted by Adamson *et al.*[11] also included younger brothers with correspondingly higher prevalence, which may be a chance finding. Thirteen brothers, a relatively high number, had already had aneurysms diagnosed. In a community which had not been so well monitored medically these previously diagnosed AAA would have been discovered only by deliberate sibling screening. In the Netherlands it is common for patients to ask their surgeon about the risk to their siblings.

The compliance rate in this study was remarkably high (210 of 269) in comparison to attendance rates in cervical cancer and breast cancer screening programmes. The siblings of AAA patients are much older than the women invited for breast and cervical cancer screening programmes. Having a sibling who has had a complicated operation for an AAA appears to be a factor influencing attendance. Another difference in this screening programme was the means used to issue the invitation. The first telephone contact with the brothers allowed for many questions to be answered, which would not have been possible if invitations had been sent by mail. Invitations by telephone are time-consuming but seem to be worthwhile.

Brothers of aneurysm patients have a high prevalence of aortic aneurysms and, until national population aneurysm screening programmes can be agreed, such targeted screening is worthwhile.

Role of saphenous vein surgery in the treatment of venous ulceration

J. M. SCRIVEN, T. HARTSHORNE, A. J. THRUSH*, P. R. F. BELL, A. R. NAYLOR and N. J. M. LONDON

*Departments of Surgery and *Medical Physics, University of Leicester, Leicester, UK*
Correspondence to: Mr J. M. Scriven, Department of Surgery, Clinical Sciences Building, Leicester Royal Infirmary, Leicester LE2 7LX, UK

Background This paper describes local anaesthetic saphenous disconnection in elderly patients for the treatment of venous ulceration in legs with either saphenous venous reflux alone or in combination with deep venous reflux.

Methods Ambulatory venous pressure was measured in 16 legs with saphenous vein reflux alone and in nine legs with combined deep and saphenous venous reflux before, immediately after and 3 months after saphenofemoral or popliteal disconnection. Ulcer area was measured by computerized planimetry before surgery and at 1 and 3 months after operation. No compression bandages or hose were applied after surgery unless the ulcers had not begun to heal after 1 month.

Results In legs with saphenous reflux alone all ulcers healed without compression bandages at a median of 81 (range 14–253) days and the pressure relief index (PRI) improved significantly both after surgery and at follow-up. None of the ulcers in the nine limbs with saphenous and deep venous reflux healed without compression bandaging and the PRI was unchanged immediately following surgery and at follow-up.

Conclusion Saphenous vein disconnection improves venous function and heals venous ulcers without compression bandaging if the deep veins are normal. This procedure under local anaesthetic may be particularly suitable for elderly patients, but long saphenous vein stripping should be added in young patients.

Venous ulceration results from prolonged venous hypertension[1]. In up to 57 per cent of cases this is due to saphenous vein reflux alone but in up to 32 per cent of cases there is, in addition, deep vein reflux[2]. The role of surgical correction of saphenous vein reflux as a therapeutic manoeuvre in the treatment of venous ulceration has previously been disregarded[3,4]. Darke and Penfold[5] have demonstrated that saphenous vein ligation with stripping to the knee (combined with postoperative compression in one-third of cases) results in ulcer healing if the deep veins are normal, with associated improvement in ambulatory venous pressure[6]. Controversy exists regarding the role of saphenous vein surgery when there is co-existing deep venous reflux. Scurr[7] has advocated saphenous vein surgery in this situation, whereas Mayberry *et al.*[8] consider that this approach is unproven. The principle behind the treatment of venous ulceration is to reduce venous hypertension, and therefore stripping of the saphenous vein may not be mandatory. All previous reports have included saphenous vein stripping and/or postoperative compression therapy in addition to saphenous vein disconnection. The aim of this study, therefore, was to examine the safety and efficacy of local anaesthetic day-case saphenofemoral or popliteal disconnection without stripping the saphenous vein or use of postoperative compression in ulcerated limbs with isolated saphenous venous reflux and in those with combined deep and saphenous venous reflux.

Patients and methods

Patients with active leg ulceration were identified from those attending a venous ulcer assessment clinic[2]. Ulcers were defined as venous if the only demonstrable abnormality was venous reflux of more than 0·5 s duration with an ankle : brachial systolic pressure index of over 0·9.

The study was designed to investigate the role of local anaesthetic saphenofemoral and/or saphenopopliteal disconnection in a total of 40 legs, 20 with superficial reflux only and 20 with superficial and deep reflux. The study received local ethics committee approval. Patients had preoperative colour duplex scanning and ambulatory venous pressure (AVP) measurements recorded; these were repeated immediately after surgery (within 1 h) and at 3 months[9,10]. Venous ulcer size was measured before surgery and at 1 and 3 months after surgery. Patients were followed up for 24 months.

To assess whether the final AVP was influenced by not stripping the saphenous vein the difference between the preoperative and follow-up AVP (expressed as a percentage of the resting pressure) in legs with normal deep veins was examined and compared to the status of the saphenous vein remnant at follow-up. Each leg was classified into one of two groups. Group 1 included legs with thrombosed and/or competent saphenous veins, and group 2 included legs with reflux still present in the venous remnant. Legs that required surgery to both the long saphenous vein (LSV) and short saphenous vein (SSV) were included in group 1 only if both venous remnants were either competent or thrombosed.

Measurement of ambulatory venous pressure

AVP was measured in the standard manner[9] immediately before and after surgery i.e. within 1 h and at a 3-month follow-up visit.

From the pressure tracing obtained the resting venous pressure (RVP) (mmHg), AVP (mmHg) and time (s) to return to 90 per cent of the resting pressure (RT90) were measured. These data allowed the calculation of an overall assessment of venous calf pump function, the pressure relief index (PRI)[10].

Colour duplex imaging

A colour duplex scan of the deep and superficial veins was performed before surgery and at follow-up visit. Venous reflux was defined as the presence of reversed blood flow for more than

Paper accepted 4 September 1997

0·5 s on release of a calf squeeze distal to the segment of vein under examination.

Ulcer area

Ulcer areas were determined by computerized planimetry from tracings of the ulcer perimeter before surgery and at 1 and 3 month follow-up. Healing was determined by inspection and deemed to be complete if full re-epithelialization had occurred.

Surgery

Saphenous disconnections were performed under local infiltration anaesthesia. Reflux at the saphenofemoral junction (SFJ) was treated by flush ligation of the SFJ with formal exploration, identification, ligation and division of all tributaries. Saphenopopliteal reflux was treated by flush ligation and division of the saphenopopliteal junction (SPJ). After surgery the ulcers were dressed with a simple non-adherent dressing (Johnson and Johnson, Ascot, UK), a layer of gauze, and a graduated below-knee Tubigrip (Seton Health Care Group, Manchester, UK). If after 1 month healing had not commenced this was replaced by a four-layer compression bandage.

Statistics

Data were analysed using non-parametric paired testing (Wilcoxon matched pairs) and unpaired (Mann–Whitney *U* test) as appropriate.

Results

Patients

The study was terminated after 25 legs (24 patients) had been studied because of the poor outcome in legs with combined superficial and deep reflux. Sixteen legs had isolated saphenous vein reflux distributed as follows: LSV only, nine; SSV only, four; and LSV and SSV combined, three. Nine legs had venous reflux in the deep and long saphenous systems combined; five had duplex evidence of previous deep vein thrombosis. Deep venous reflux was present throughout the full length of the superficial femoral and popliteal veins into the calf veins in all nine legs. Patients' ages, initial ulcer area and duration at the time of surgery are given in *Table 1*.

Eighteen legs had saphenofemoral disconnection, four saphenopopliteal disconnection and three had both. All patients who had saphenopopliteal disconnection had preoperative marking of the SPJ by colour duplex imaging

Ulcer healing

All 16 ulcers in legs with isolated saphenous vein reflux began to heal within 1 month of surgery, and all healed completely at a median of 81 (range 14–253) days. None required compression bandaging.

Table 1 Characteristics of the patients and ulcers

	Initial ulcer area (cm^2)	Ulcer duration before surgery (years)	Patient age (years)
Saphenous reflux only ($n = 16$)*	9 (3–14)	2 (1–6)	73 (56–77)
Deep and superficial reflux combined ($n = 9$)*	18 (9–92)	2 (1–3)	77 (63–85)
P†	0·02	0·59	0·41

*Values are median (range). †Mann–Whitney *U* test

None of the nine ulcerated legs with combined deep and saphenous vein reflux had started to heal by 1 month. Median ulcer area had increased from 18 (range 9–92) cm^2 to 24 (15–126) cm^2 ($P = 0{\cdot}01$, Wilcoxon matched pairs). All nine legs were subsequently treated with four-layer compression bandaging. After a median follow-up of 16·5 (range 10–24) months, three ulcers had healed at 136, 168 and 196 days. The remaining six were unhealed.

Venous function

The PRI (*Fig. 1*) increased significantly immediately after surgery and at follow-up visit in legs with isolated saphenous reflux. In legs with deep and saphenous reflux combined the PRI remained unchanged immediately after surgery and at follow-up visit.

The RT90 (*Fig. 2*) lengthened significantly immediately after surgery in legs with isolated saphenous reflux. This lengthening in the RT90 was maintained but not improved at follow-up visit. In legs with combined deep and saphenous reflux there was no change in the RT90 after surgery or at follow-up visit.

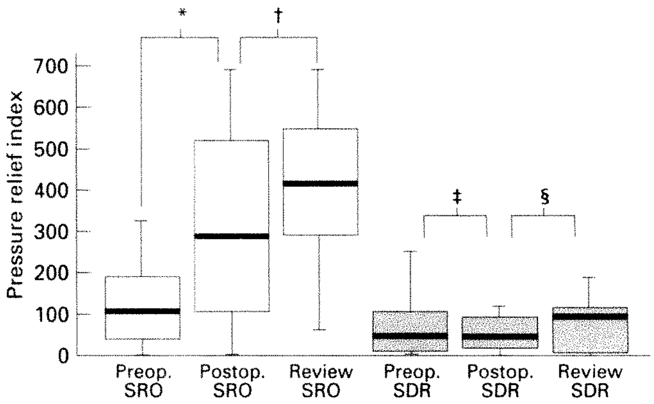

Fig. 1 Pressure relief index before and after surgery and after 3 months. SRO, saphenous reflux only; SDR, saphenous and deep reflux combined. Bars, median; box, interquartile range; whiskers, range. *$P = 0{\cdot}001$; †$P = 0{\cdot}04$; ‡$P = 0{\cdot}58$; §$P = 0{\cdot}25$ (Wilcoxon matched pairs)

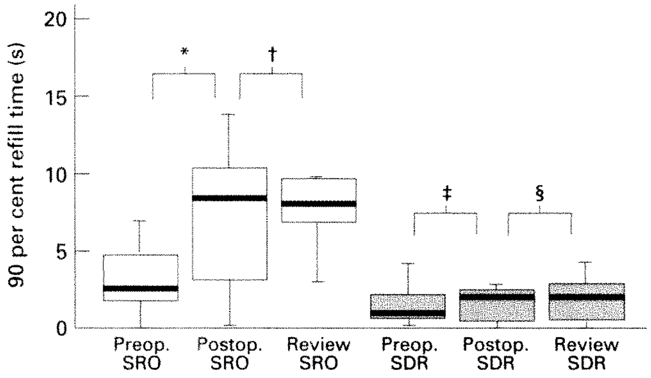

Fig. 2 Ninety per cent refill time before and after surgery and after 3 months. SRO, saphenous reflux only; SDR, saphenous and deep reflux combined. Bars, median; box, interquartile range; whiskers, range. *$P = 0{\cdot}003$; †$P = 0{\cdot}27$; ‡$P = 0{\cdot}80$; §$P = 0{\cdot}42$ (Wilcoxon matched pairs)

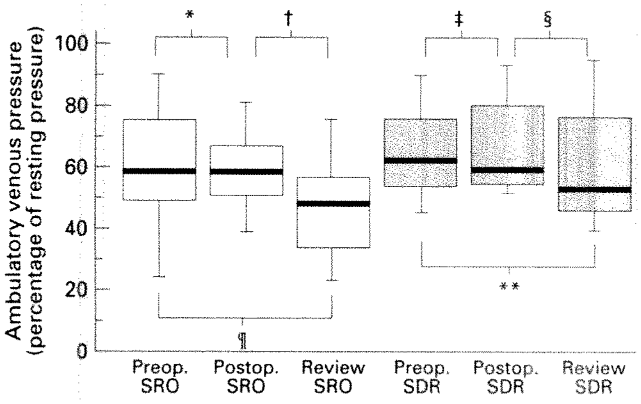

Fig. 3 Ambulatory venous pressure (as a percentage of resting pressure) before and after surgery and after 3 months. SRO, saphenous reflux only; SDR, saphenous and deep reflux combined. Bars, median; box, interquartile range; whiskers, range. *$P = 0{\cdot}55$; †$P = 0{\cdot}003$; ‡$P = 0{\cdot}44$; §$P = 0{\cdot}35$; ¶$P = 0{\cdot}001$; **$P = 0{\cdot}61$ (Wilcoxon matched pairs)

The AVP (*Fig. 3*) was unchanged after surgery in legs with saphenous reflux only but at follow-up visit had significantly decreased. The AVP remained unchanged throughout the study in legs with combined deep and saphenous reflux.

Distribution of venous reflux at follow-up

Of the 16 legs with isolated saphenous vein reflux, 12 LSVs and seven SSVs were ligated. At follow-up visit all 12 LSVs had been disconnected adequately at the SFJ and of the unstripped remnants, five had thrombosed, three remained incompetent, three had become competent and one LSV was not visualized fully. Of the seven SSV ligations, all had been disconnected, two SSV remnants had thrombosed, three regained competency, one remained incompetent and one was found to have a recurrent connection with the deep venous system. All of the deep veins in this groups of limbs remained fully patent and competent.

Median difference in preoperative and follow-up AVP in those limbs with normal deep veins was as follows: group 1 (thrombosed or competent LSV or SSV) 16·5 (range 5–37) per cent and group 2 (incompetent LSV or SSV) 10 (range −2 to 30) per cent ($P = 0{\cdot}44$, Mann–Whitney U test).

Considering legs with combined deep and saphenous venous reflux, all nine LSVs were adequately disconnected at the SFJ and all deep veins remained patent and incompetent. The states of the LSV remnants were: four thrombosed, three remained incompetent, one had recurrent reflux from the groin and one was visualized inadequately. None had regained their competency.

Discussion

This study examined the efficacy of saphenofemoral and/or popliteal disconnection alone without stripping the saphenous vein and without postoperative compression. This is important for three reasons. First, if correction of venous hypertension is of prime importance in achieving ulcer healing, then stripping the LSV may be unnecessary. Second, saphenous disconnection alone lends itself to local anaesthetic day-case surgery and does not carry the morbidity of LSV stripping. Third, postoperative compression was avoided which allowed full evaluation of the surgical procedure itself.

In the absence of deep venous reflux, saphenous disconnection alone results in healing without the need for compression hose or bandages. This was accompanied by an improvement in the PRI in the immediate postoperative phase and a further improvement 3 months following surgery. The parameters that constituted the PRI behaved differently. The RT90 lengthened immediately after operation and although this was maintained at 3 months it did not improve further. The AVP, however, failed to improve immediately after surgery but at follow-up was significantly lower than either the preoperative or the postoperative value. This supports a theory of volume overload[11,12] on the calf muscle pump in that saphenous disconnection immediately removes the source of venous reflux (reflected in the lengthening of the RT90) but it takes time for the AVP to drop to a significantly lower value. This suggests that for the calf muscle pump to regain its function, some degree of recovery and accommodation to the reduced reflux load is required, hence the delay in obtaining a reduced AVP. It is also noteworthy that three of the seven LSV remnants regained their competence suggesting that reducing the refluxing volume allows the veins to regain their tone, allowing opposition of vein valve cusps.

The haemodynamic changes demonstrated by this study suggest that saphenous vein stripping is unnecessary to achieve ulcer healing and improved venous function if the deep veins function normally. There was no detrimental haemodynamic effect of leaving a refluxing LSV remnant behind. However, it has been shown that the incidence of recurrent reflux at the SFJ[13] is greater if the SFJ is disconnected without stripping. Although the patients in this study were elderly, many venous ulcers begin in young patients who require a durable surgical procedure to minimize venous reflux recurrence and hence ulcer recurrence. In younger patients with venous ulceration and isolated saphenous reflux saphenous disconnection and stripping under general anaesthesia is the preferred option. The data presented here are drawn from a small number of patients; the durability and effect on ulcer recurrence rates need further evaluation.

It has been recommended that in the presence of coexisting deep reflux, saphenous reflux should be corrected as far as possible for venous ulceration[7]. In this study saphenous disconnection had no effect on ulcer area or venous haemodynamics in legs with combined deep and saphenous vein reflux.

Local anaesthetic, day-case saphenous disconnection is safe in the elderly. Providing the deep veins were normal, all ulcers in this study healed without postoperative compression. If deep venous reflux extended below the knee, saphenous disconnection had no effect on venous haemodynamics and all ulcers failed to heal without compression.

Background It has been suggested that reperfusion of the acutely ischaemic lower limb alters gut permeability. The effect of lower limb ischaemia–reperfusion on systemic endotoxin and antiendotoxin antibody concentrations and the incidence of bacterial translocation was investigated.

Methods Systemic endotoxin and antiendotoxin antibody concentrations were measured in five groups of male Wistar rats: control, after 3 h of bilateral hind limb ischaemia alone, and after 3 h of bilateral hind limb ischaemia followed by 1, 2 or 3 h of reperfusion. A second experiment examined translocation of indigenous bacteria following 2 h of reperfusion in a similar model.

Results Ischaemia followed by reperfusion for 1, 2 or 3 h caused a significant increase in plasma endotoxin concentration to mean(s.e.m.) 10·0(3·0), 44·8(19·2) and 20·2(6·2) pg/ml compared with that in control animals (2·58(0·91) pg/ml) or animals in the ischaemia alone group (1·2(0·9) pg/ml) ($P < 0{\cdot}05$). This was associated with a significant reduction in endogenous antiendotoxin antibody (immunoglobulin (Ig) G and IgM) concentration. No significant bacterial translocation was detected in any of the groups studied.

Conclusion These results demonstrate that a remote and isolated ischaemia–reperfusion injury to the lower limb, in the absence of infection or bacterial translocation, causes endotoxaemia. Further studies are needed to evaluate the role of endogenous antiendotoxin antibodies in this situation.

Multiple organ dysfunction syndrome (MODS) is a significant cause of morbidity and death after trauma and major vascular surgery such as abdominal aortic aneurysm surgery[1–3]. Until recently it was generally accepted that MODS was a complication of uncontrolled infection or a manifestation of an occult septic focus, but it is now clear that MODS can develop in the absence of infection[4,5]. The development of sepsis syndrome and MODS in patients after trauma, major surgery or critical illness in the absence of an identifiable focus of infection has lead to the hypothesis that micro-organisms from the intestinal lumen may be the source of bacteria and that endotoxin is involved in the pathogenesis and pathophysiology of these syndromes[6].

The gastrointestinal tract is normally inhabited by a large collection of microbial species and high concentrations of endotoxins[7,8]. To protect the host from being invaded by its own flora or their toxins the gut is equipped with efficient defence mechanisms which constitute 'the gut barrier'. These include a normal ecological balance of gastrointestinal microflora that competitively inhibit overgrowth, and hence translocation, of any particular species and an intact intestinal mucosa that provides a physical barrier to translocation of particles including antigens and bacteria[9]. Immune defences such as gut-associated lymphoid tissue, Kupffer cells of the liver and serum immunoglobulins act as a second line of defence should breach of the physical barrier occur[10]. It has been suggested that circulating endogenous antiendotoxin antibodies can bind and neutralize endotoxin escaping from the gut. This was demonstrated by a decrease in their plasma concentration following exposure to endotoxin[11]. Serum immunoglobulins can also opsonize translocating bacteria to increase their clearance from lymphoid organs and the bloodstream thereby decreasing their systemic dissemination[12].

Clinical studies have suggested that gut permeability is altered following major vascular surgery and endotoxin has been demonstrated in plasma of patients undergoing abdominal aortic aneurysm replacement[13,14]. The link between lower limb ischaemia–reperfusion injury, gut permeability and the development of remote organ dysfunction following abdominal aortic aneursym surgery is unclear. The objectives of this study were to determine the effect of ischaemia–reperfusion injury of the lower limb on systemic endotoxin and endogenous antiendotoxin antibody concentrations, and bacterial translocation in a rodent model.

Materials and methods

Animal model

Adult male Wistar rats weighing 300–350 g obtained from a breeding colony were used in the study. Animals were kept under standard conditions and had free access to standard rat chow (R. Morton, Ballymena, UK) and water *ad libitum* until the morning of the experiment. The animals were anaesthetized with subcutaneous ketamine 80 mg/kg and xylazine 8 mg/kg. Hydration of the animals was maintained by injection of sterile 0·9 per cent sodium chloride (Antigen Pharmaceuticals, Roscrea, Ireland) 3 ml per kg per h subcutaneously. Using a heating lamp, body temperature was kept at 37°C. Bilateral hind limb ischaemia was induced by applying rubber band tourniquets high

Paper accepted 6 November 1997

around each thigh as described originally by Rosenthal[15]. At the end of the ischaemic period reperfusion of the limbs was achieved by releasing the tourniquets. All procedures involving animals were carried out in accordance with the regulations of the United Kingdom Animals (Scientific Procedures) Act, 1986.

Experiment 1

Blood samples were taken from five groups of animals (12 in each group): control (6 h of general anaesthesia) (group 1); after 3 h of bilateral hind limb ischaemia alone (group 2); and after 3 h of bilateral hind limb ischaemia followed by reperfusion for 1, 2 or 3 h (groups 3, 4 and 5) (*Fig. 1*).

Blood sampling. At the time of blood sampling the chest wall was cleansed with chlorhexidine in spirit, a 1-cm disc of skin was excised and a butterfly needle connected to a 10-ml syringe was then used to obtain a blood sample by direct cardiac puncture. Blood samples were collected into heparinized (20 units per ml blood) sterile pyrogen-free tubes. Samples were immediately transferred on ice to be centrifuged at 200 r.p.m. (at 4°C) for 10 min. Plasma was then aliquoted into sterile cryotubes (Nunc; Intermed, Roskidle, Denmark) and stored at −70°C until the time of assay for endotoxin and antiendotoxin antibody.

Endotoxin assay. Bacterial endotoxin was quantified in duplicates using an endpoint chromogenic Limulus Amoebocyte Lysate assay (Quadratech, Epsom, UK). Samples were diluted (1:10 with sterile pyrogen-free water and heat-treated at 75°C for 10 min to remove plasma inhibitors. The concentration of endotoxin in the samples was calculated from a standard curve which was generated in 10 per cent normal rat plasma using *Escherichia coli* endotoxin (0111:B4) supplied with the kit and similarly treated. The amount of endotoxin in the sample was determined photometrically at 405 nm. The assay had a sensitivity of 8·3 pg/ml and range of 8·3–100 pg/ml. Each aliquot was assayed for endotoxin only once. If the assay gave poor duplicates or high values, which may indicate contamination, a fresh aliquot of the same sample was tested. The interassay and intra-assay coefficients of variation were less than 10 per cent and less than 15 per cent, respectively. The assay was always undertaken by the same individual who was specifically assigned to measuring endotoxin.

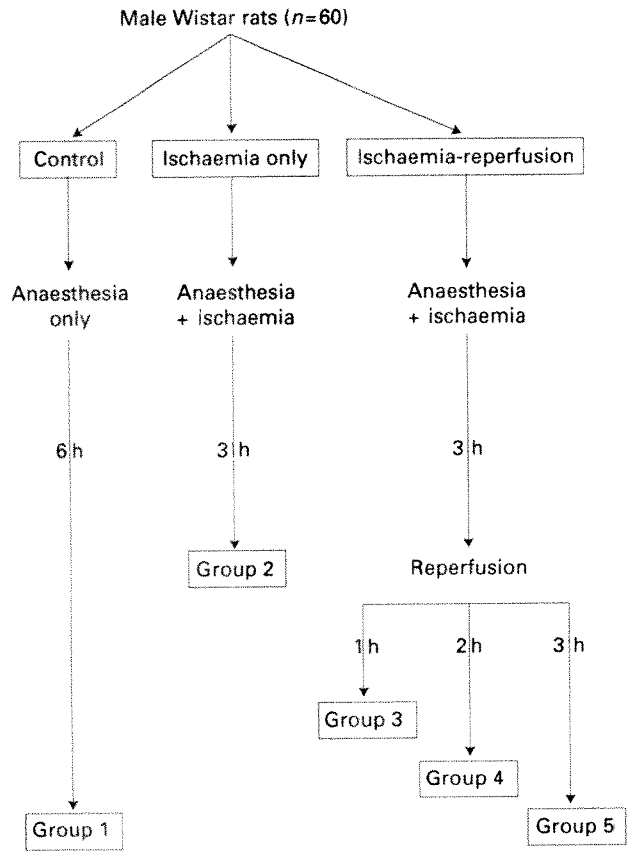

Fig. 1 Experimental design

Antiendotoxin antibody assay. The 'EndoCAb' enzyme-linked immunosorbent assay, which measures antibody levels to the core glycolipid region of lipopolysaccharide, was used to measure antiendotoxin antibody levels[16]. The microplates (G.R. Barclay, Scottish Blood Transfusion Centre, Edinburgh, UK) were previously coated with a 'cocktail' of core lipopolysaccharide from rough mutants of a number of bacteria complexed with polymyxin and then blocked with 5 per cent bovine serum albumin. Plasma samples were diluted 1:200 using phosphate buffered saline, pH 7·4 containing 0·05 per cent Tween (Sigma, Poole, UK), 0·5 per cent bovine serum albumin (Sigma) and 4 per cent polyethylene glycol (BDH Chemicals, Poole, UK). A normal plasma dilution curve was obtained by using plasma at a range of dilution from 1:50 to 1:1600. Standards and samples were added in duplicate to the plate at 100 μl per well. The plate was incubated for 1 h at room temperature with continuous shaking. A 1:250 dilution of the antirat immunoglobulin (Ig) G peroxidase or 1:500 dilution of the antirat IgM peroxidase (Serotec, Oxford, UK), prepared in the above diluent, was then added to each well (100 μl) for 1 h at room temperature with continuous shaking. Following this, 100 μl 3,3,5,5 tetramethylbenzidine substrate (Sigma) was added to each well for 10 min and the reaction stopped using sulphuric acid 2 mol/l. The plate was then read on a Thermomax kinetic reader (Molecular Devices, Crawley, UK) at an absorbance of 450 nm and the results calculated as a percentage of the normal range.

Experiment 2

Bacterial translocation was studied in three groups of animals: group 1, control ($n = 5$); group 2, 3 h of bilateral hind limb ischaemia alone ($n = 8$); and group 3, 3 h of bilateral hind limb ischaemia followed by 3 h of reperfusion ($n = 8$).

Collection of samples. The fur of the anaesthetized animal was cleansed with chlorhexidine and a midline laparotomy was performed. A peritoneal swab was taken to check for contamination. Using aseptic techniques the following samples were taken: (1) portal blood sample from the portal vein, (2) systemic blood sample from the inferior vena cava, (3) mesenteric lymph nodes, (4) spleen and (5) liver. These were collected into prereduced nutrient broth and the weight of each tissue sample was noted.

Peritoneal swabs. Swabs were plated out on blood, chocolate and MacConkey agar (Oxoid-Unipath, Basingstoke, UK) for aerobic culture and prereduced blood agar for anaerobic culture. They were also placed in cooked meat broth (Gibco Life Technologies, Paisley, UK) for 24 h at 37°C before plating out for aerobic and anaerobic culture as above. If the peritoneal swab was positive the animal was considered to have been contaminated and was excluded from the study.

Tissue samples. Tissue samples were homogenized in 2 ml nutrient broth and 0·1-ml aliquots of homogenate were cultured anaerobically on prereduced blood agar and aerobically on blood, chocolate and MacConkey agar. All aerobic plates were incubated for 48 h at 37°C and anaerobic plates were incubated for 5 days in an anaerobic cabinet at 37°C (Concept 300 Anaerobic Workstation; Ruskin Technology, West Bradford, UK). A 0·1-ml aliquot was also placed into cooked meat broth (Gibco) for 24 h at 37°C. This was then plated out and cultured aerobically and anaerobically as above. All plates were read and positive cultures were Gram-stained and identified using standard bacteriological techniques.

Blood cultures. Blood cultures were processed using the Bac-T/Alert blood culture system (Organon Teknika, Durham, North Carolina, USA). This is a sensitive and reliable automated system which can rapidly detect most micro-organisms[17,18]. Any positive cultures were plated out on the appropriate aerobic or anaerobic media as described above.

Micro-organism quantitation. The number of micro-organisms per gram of tissue was calculated using the formula

$$\frac{n \times 2 \times 10}{w}$$

where n is the number of colonies isolated, multiplied by 2 for the 2 ml of nutrient broth and 10 for the 0·1-ml inoculum, and w is the weight of tissue in grams.

Statistical analysis

Results are expressed as mean(s.e.m.). Kruskal–Wallis analysis of variance was used to detect differences between groups and statistical comparisons were made using the Mann–Whitney U test with a level of significance of $P < 0·05$.

Results

Plasma endotoxin concentration

No significant concentrations of endotoxin were detected in the plasma of controls or animals in the ischaemia alone group. Plasma endotoxin concentrations increased significantly in animals subjected to ischaemia followed by reperfusion compared with those in controls or animals in the ischaemia alone group ($P < 0·05$) (*Table 1*). Significantly higher concentrations of endotoxin were detected in the majority, but not all, of the reperfused animals which accounted for the high standard error of the mean observed.

Plasma antiendotoxin antibody concentration

A significant decrease in plasma concentrations of antiendotoxin antibody IgG and IgM was observed in animals following 3 h of ischaemia alone compared with those in control animals ($P < 0·05$). Plasma concentrations of both IgG and IgM antiendotoxin antibodies decreased significantly in animals subjected to ischaemia followed by reperfusion compared with those in controls ($P < 0·05$) (*Table 2*).

Bacterial translocation

Peritoneal swabs were sterile in all samples. No evidence of bacterial translocation was detected in any animal in the control group. Bacterial translocation occurred to mesenteric lymph nodes and liver in one animal in the ischaemic group (Gram-positive bacilli) and to the mesenteric lymph nodes in one animal in the ischaemia–reperfusion group (Gram-positive bacilli and coagulase-negative staphylococci). No bacterial growth was detected in the portal or the systemic blood in any group.

Discussion

The findings in this study concur with previous observations that ischaemia–reperfusion injury to the lower limb leads to systemic endotoxaemia[19]. It has been suggested that the gut is the most likely source of endotoxaemia. An increase in intestinal permeability has been reported following abdominal aortic aneurysm surgery, a procedure that may lead to colonic ischaemia consequent upon ligation of the inferior mesenteric artery[13,14,20]. However the findings in this study indicate that isolated ischaemia–reperfusion injury to the lower limb *per se* can lead to systemic endotoxaemia. The mechanism involved in the development of endotoxaemia is not entirely clear. An increase in intestinal permeability to macromolecules has been observed following ischaemia–reperfusion injury to the hind limb[21]. Similar alteration in intestinal permeability has been reported following other forms of trauma and has been attributed to generalized permeability damage termed 'whole body inflammation'[22–25].

Endotoxin is the lipopolysaccharide component of the cell membrane of Gram-negative bacteria. It has a wide range of toxic biological actions and is a recognized potent activator of various cellular and humoral pathways including the complement and coagulation cascades[26,27]

Table 1 Effect of ischaemia–reperfusion on plasma endotoxin concentration

	Control ($n = 12$)	3 h ischaemia ($n = 12$)	3 h ischaemia + 1 h reperfusion ($n = 12$)	3 h ischaemia + 2 h reperfusion ($n = 12$)	3 h ischaemia + 3 h reperfusio ($n = 12$)
Endotoxin (pg/ml)	2·5(0·9)	1·2(0·9)	10·0(3·0)*	44·8(19·2)*	20·2(6·2)*

Values are mean(s.e.m.). $*P < 0·05$ *versus* control (Mann–Whitney U test)

Table 2 Effect of ischaemia–reperfusion on plasma antiendotoxin antibody concentration

	Control ($n = 12$)	3 h ischaemia ($n = 12$)	3 h ischaemia + 1 h reperfusion ($n = 12$)	3 h ischaemia + 2 h reperfusion ($n = 12$)	3 h ischaemia + 3 h reperfusio ($n = 12$)
IgG (% of control value)	100 (11·2)	77·9 (9·9)*	71·1 (3·6)*	67·1 (3·1)†	68·4 (3·1)†
IgM (% of control value)	100 (8·1)	80·5 (9·7)*	70·1 (8·9)†	75·8 (8·9)*	79 (8·9)

Values are mean(s.e.m.). Ig, immunoglobulin. $*P < 0·05$, $†P < 0·005$ *versus* control (Mann–Whitney U test)

By activating macrophages and polymorphonuclear neutrophils endotoxin induces the production of an array of inflammatory mediators including different cytokines[28,29]. Together with these mediators, endotoxin causes metabolic derangement, vascular endothelial damage and cardiovascular changes that may result in hypotension and shock[30,31].

Although bacterial translocation has been demonstrated in a variety of other settings, it has not been observed following reperfusion of the ischaemic extremities despite the presence of endotoxaemia[9,32–36]. The clinical significance of bacterial translocation and whether it plays a role in the pathophysiology of MODS remains unclear. Deitch *et al.*[34] studied the relationship between endotoxin, intestinal mucosal injury and bacterial translocation. They concluded that the gut, under certain circumstances, may serve as an important port of entry for bacteria. Peitzman *et al.*[37] were unable to find any relationship between the development of sepsis and MODS and positive mesenteric lymph node culture in critically ill trauma patients. Other workers have shown that the occurrence of endotoxaemia is a more sensitive predictor of the development of sepsis syndrome than bacteraemia[38,39]. This may be due to the fact that translocated bacteria are killed in the mesenteric lymph nodes while endotoxin is released and disseminated[40]. Furthermore, endotoxin has been shown to permeate through the bowel more easily than intact Gram-negative bacteria[38]. This indicates that the detection of endotoxin may be clinically more significant than bacteraemia. This concept is supported by several clinical studies which have shown that, although selective gut decontamination causes dramatic reduction in colonization and effectively prevents bacterial translocation from the gut, it does not significantly reduce the mortality rate or hospital stay in critically ill patients[41]. In a study of patients with septic shock, endotoxaemia occurred in 43 per cent of patients but only 26 per cent of patients with endotoxaemia had Gram-negative bacteraemia[42]. Similar findings were reported in other studies[43,44].

Antibodies produced by the host against the inner core glycolipid (EndoCAb) offer some protection against different strains of bacteria and the toxic effects of the lipopolysaccharide[45]. The decrease in endogenous antibodies (EndoCAb) observed in animals following lower limb ischaemia–reperfusion provides further evidence in support of the development of endotoxaemia. Antiendotoxin antibodies are consumed by the formation of endotoxin–antibody complexes thus neutralizing endotoxin and lowering its plasma concentration. The depletion of these endogenous EndoCAb antibodies has been found to be associated with significantly higher endotoxin levels in patients with sepsis. Moreover, patients with a low IgG EndoCAb level on admission had a significantly higher mortality rate[44]. This implied that endogenous EndoCAb concentration may be of value in predicting outcome in patients with sepsis syndrome. The fact that 74 per cent of patients had normal circulating levels of these antibodies suggests that the low level of antibody is a reflection of the degree of endotoxaemia rather than a cause of it.

It is worth noting that a reduction in antiendotoxin antibodies was also observed in animals that were ischaemic but not reperfused although there was no accompanying increase in endotoxin in these animals. A possible explanation is that some degree of reperfusion and endotoxaemia occurred in these animals before tourniquet release owing to incomplete ischaemia of the limbs. A significant decrease in endogenous EndoCAb has been reported following major surgery and it is conceivable that the decrease in antiendotoxin antibodies was part of a generalized decrease in immunoglobulin levels and not specific for endotoxin[11]. To elucidate this further, experiments should be carried out in animals immunized against tetanus toxoid, with measurement of antitetanus toxoid antibodies, in addition to antiendotoxin antibodies, as a marker of the generalized decrease in plasma immunoglobulins.

In conclusion, this study shows that endotoxaemia may occur following reperfusion of ischaemic hind limbs. Bacterial translocation does not seem to be a prerequisite for endotoxaemia. Studies of the systemic inflammatory response and end-organ function are currently under way to determine whether endotoxaemia contributes to the systemic complications observed following lower limb ischaemia–reperfusion in patients undergoing abdominal aortic aneurysm surgery.

Prospective randomized controlled trial to compare skin staples and polypropylene for securing the mesh in inguinal hernia repair

I. W. MILLS, I. M. McDERMOTT and D. A. RATLIFF

Department of Surgery, Northampton General Hospital NHS Trust, Cliftonville, Northampton NN1 5BD, UK
Correspondence to: Mr D. A. Ratliff

Background The Lichtenstein tension-free repair has become the standard method for repairing inguinal hernia in many surgical units. This study compared two methods of mesh fixation.

Methods Fifty men undergoing unilateral primary Lichtenstein inguinal hernia repair under general anaesthesia were randomized into two groups. In the control group polypropylene mesh was secured with 2/0 polypropylene sutures and the skin closed with subcuticular 3/0 polydioxanone. In the study group polypropylene mesh was secured with skin staples and the skin was closed with staples from the same staple gun. Duration of the operation was recorded. Early follow-up was achieved by patient review at 6 weeks and postal questionnaire at 12 weeks.

Results The operation was significantly shorter when staples were used (median 20 min 0 s *versus* 29 min 30 s, $P < 0{\cdot}001$). There was no significant difference in the incidence of postoperative complications or pain score. The study group reported earlier return to normal activity (4 weeks 0 days *versus* 6 weeks 2 days, $P < 0{\cdot}01$) although there was no difference in the time taken to return to work or driving.

Conclusion The use of skin staples to secure mesh in the Lichtenstein inguinal hernia repair significantly reduced the duration of the operation and was as effective as conventional mesh fixation with polypropylene in the short term.

The Lichtenstein repair is a tension-free inguinal hernia repair in which a sheet of polypropylene mesh is used to strengthen the transversalis fascia[1]. The standard way of securing the mesh in position on the posterior wall of the inguinal canal is with polypropylene sutures. A technique has been described in which skin staples are used for anchoring the mesh in position and early results have been favourable[2]. Concerns have been expressed, however, that the use of staples may lead to entrapment neuropathy[3,4], increased rate of wound infection[4], potential vascular injury[3,5,6] and increased cost[3]. This modification of the Lichtenstein technique was investigated in a randomized, prospective controlled trial to address these concerns and establish whether the use of staples leads to an effective repair.

Patients and methods

Fifty patients having elective repair of a unilateral primary inguinal hernia were entered into the trial. Informed consent was obtained. Patients were randomized either to the control group (where mesh was secured with polypropylene sutures) or the study group (where the mesh was secured with staples) in the operating room by sealed envelope.

All operations were performed under general anaesthesia by a consultant surgeon (D.A.R.). An ilioinguinal nerve block was inserted with bupivacaine 0·5 per cent by the anaesthetist and a single dose of intravenous co-amoxiclav 1·2 g was administered immediately before the operation began.

Direct hernia sacs were plicated unless very small, when they were reduced unopened. Indirect sacs were dissected from the spermatic cord and then divided, transfixed and excised. A sheet of polypropylene mesh (11 × 6 cm) was cut to shape and laid over the posterior wall of the inguinal canal so that it overlapped the pubic tubercle by at least 1 cm medially, extended superiorly to lay over the conjoint tendon and to a point at least 2 cm lateral to the internal ring. In the control groups this was fixed in position by a continuous suture of 2/0 polypropylene along the inguinal ligament inferiorly from the pubic tubercle to the lateral edge of the mesh. Interrupted polypropylene sutures were then placed medially and superiorly into the internal oblique and transversalis muscles. The spermatic cord was passed through the slit in the mesh. Lateral to it the overlapping free edges of the mesh were sutured together with two interrupted polypropylene sutures. In the study group the positioning of the mesh was identical but a Proximate RH Rotating Head Skin Stapler (Ethicon, Edinburgh, UK), containing 35 preloaded stainless steel staples, was used to secure it. A staple was placed into the pubic tubercle with between seven and nine staples along the inguinal ligament placed 1–2 cm apart. A further eight to ten staples were placed in the internal oblique and transversalis muscles medially and superiorly and the overlapping free edges of the mesh were stapled together with two staples lateral to the cord. In both groups the external oblique aponeurosis was closed with a continuous suture of 2/0 Vicryl (Ethicon, Edinburgh UK) and the subcutaneous tissues were then approximated with the same suture. Skin closure was completed in the control group using a continuous suture of subcuticular 3/0 polydioxanone which was subsequently left in place. In the study group skin closure was completed using staples from the same staple gun and these were removed 7 days after operation.

The time taken from the first incision to the beginning of the hernia repair (defined as start of preparation of the mesh) and from the beginning of the mesh insertion to completion of skin closure were recorded to the nearest 5 s.

Patients were provided with a supply of oral coproxamol after operation and were discharged home when considered safe. Some patients were kept in hospital overnight for social, as opposed to surgical, reasons.

All patients were reviewed in an outpatient clinic 6 weeks after operation. Some 12 weeks after operation they were asked to complete a standard questionnaire and return by post. This requested information concerning complications of surgery, general practitioner (GP) call out or visit following discharge and time taken to return to work, normal activities and driving. Patients were also asked on the questionnaire to assess how much pain they had suffered after the operation on a 100-mm visual analogue scale. Patients who did not return the question-

Paper accepted 6 September 1997

naire within 4 weeks were contacted by telephone and reminded to complete and return it.

Statistical analysis was performed using the χ^2 test with Yates' correction, Fisher's exact probability test and the Mann–Whitney *U* test.

Results

Patients

There were 25 patients in each group. The distribution of age, side of hernia and type of hernia was well matched between groups (*Table 1*). Forty-eight patients attended for outpatient review at 6 weeks and 46 patients completed the questionnaire.

Duration of surgery

The median duration of operation in the study group was 20 min 0 s compared with 29 min 30 s in the control group ($P < 0{\cdot}001$; *Table 2*). This difference was accounted for by the difference in time from the beginning of the mesh insertion to the end of operation.

Length of postoperative hospital stay

Seven patients in each group were treated as day cases, while 13 patients in the study group and 11 patients in the control group were discharged on the first postoperative day. Two patients in the control group had to be kept in hospital for more than 2 nights after operation: one for 5 days because of pain and poor social support and one for 7 days because of the development of a large scrotal haematoma.

Table 1 Clinical details

	Staples	Polypropylene
Median (range) age (years)	57·5 (21–82)	61 (18–75)
Type of hernia		
Right : left	13 : 12	16 : 9
Direct : indirect	7 : 18	8 : 17

Complications

Three patients in the study group and six in the control group suffered a minor complication. Four patients developed a wound haematoma (two in each group) but none required reoperation and all settled spontaneously. The two superficial wound infections and cellulitis of the hand, at the site of an intravenous cannula, resolved following a short course of oral antibiotics (all in the control group). There were no cases of mesh infection. One patient in the study group who developed urinary retention after operation had a urethral catheter inserted by his GP and subsequently had a successful trial without catheter at home. One patient in the control group has persistent groin pain and remains under review with a possible diagnosis of nerve entrapment. There was no hernia recurrence during the short follow-up period in either group.

Postoperative pain

There was no difference in pain scores between the two groups (*Table 3*). Only one patient still had pain 12 weeks after operation (control group).

Postoperative rehabilitation

Ten of the 24 patients in the control group available for follow-up consulted their GP after operation compared with seven of 24 patients in the study group (*Table 3*). One of these in each group necessitated a GP's visit to the patient's home while the remaining consultations took place in the GP's surgery. Two of the patients in the study group visited their GP for removal of the staples alone while all the other patients in this group had staples

Table 2 Duration of hernia repair

	Staples time (min + s)	Polypropylene time (min + s)	*P*
Start to beginning of mesh insertion	13·40 (9·00–25·30)	12·30 (7·50–19·45)	>0·1
Beginning of mesh insertion to end	7·20 (5·40–11·25)	17·45 (10·05–25·45)	<0·001
Total operation time	20·00 (16·00–33·15)	29·30 (24·00–43·45)	<0·001

Values are median (range)

Table 3 Postoperative course

	Staples	Polypropylene	*P*
Pain score*	32 (0–84) (*n* = 23)	47·5 (0–100) (*n* = 20)	>0·1
No. of GP consultations	7 of 24	10 of 24	>0·2

Complication	2	3	
Pain	0	3	
Removal clips	2	0	
Off-work certificate	1	2	
Check-up	2	2	
Return to normal activity*†	4 (0·6–12) (*n* = 23)	6·2 (0·5–14) (*n* = 22)	<0·01
Return to work*†	5·4 (1–13) (*n* = 14)	6 (0·4–12) (*n* = 11)	>0·1
Return to driving*†	3 (1–8) (*n* = 17)	3·5 (0·4–8) (*n* = 16)	>0·1

*Values are median (range); †weeks and days removed by the district nurse. This group reported earlier return to normal activity (4 weeks 0 days *versus* 6 weeks 2 days, $P < 0{\cdot}01$). There was, however, no significant difference in the time taken to return to work or driving.

Discussion

The Lichtenstein tension-free inguinal hernia repair is becoming increasingly popular in the UK because it offers an effective repair that overcomes many of the problems and criticisms associated with other techniques. It is relatively easier to learn and less technically demanding than the Shouldice repair which has until recently been the gold standard recommended by the Royal College of Surgeons of England[7]. A different way of securing the polypropylene mesh using staples has been described by Egger *et al.*[2], but has been met with some scepticism[3-6].

In the study group the staples which were left in the staple gun following mesh fixation were used to close the skin, for economic reasons. In the control group the skin was closed with a continuous subcuticular suture of polydioxanone which was previously the preferred method of skin closure. Although employment of different methods of skin closure removed the potential for a blinded study, it allowed comparison with a 'best practice' control group. All operations were performed by one consultant surgeon removing any bias that might have been attributed to grade or ability of the surgeon.

The median length of the operation was almost 10 min shorter when staples were used. This operating time compares favourably with previous reports for the Lichtenstein repair[8,9], and may be important because shorter operations may be associated with a reduced risk of wound infection and because this keeps the risk of general anaesthesia to a minimum.

The use of skin staples for securing the mesh was not associated with an increase in perioperative complications. The staples are made from stainless steel with an inert coating. The length of the prongs on the staples is 3·9 mm which appears sufficient to provide good penetration into the tissues, including the pubic tubercle, with secure fixation of the mesh. Risk of damage to major underlying vessels may be less than with insertion of conventional sutures. Accurate staple placement is facilitated by the design of the stapler, whose head rotates 360°, thereby allowing maximum visibility and improved access.

Patients in the study group reported that they returned to normal activity earlier than those in the control group. There was also a trend for patients in the study group to return to work and driving earlier, to consult their GP less and to report lower pain scores on a visual analogue scale, although none of these differences was statistically significant. This apparent earlier rehabilitation may be because patients in the study group saw the district nurse for removal of staples and thus potentially benefited from constructive and encouraging advice regarding rehabilitation. Overall, the patients' return to normal activity, work and driving in this study took longer than expected. The patients were seen and counselled before surgery by a consultant surgeon and were advised that it was likely that they should be able to return to driving after 7–10 days and normal activity and work after 2–3 weeks[10]. One explanation may be that these estimates were overcautiously interpreted by patients and their GPs[11].

This study has demonstrated that the technique of mesh fixation with skin staples in the Lichtenstein inguinal hernia repair is as effective as conventional fixation with polypropylene sutures in the short term. It also has an important advantage in significantly reducing operating time. Although the cost of consumables per operation is increased when staples are used, this cost should be carefully weighed against the more efficient use of operating time.

Lichtenstein inguinal hernia repair in a primary healthcare setting

P. M. LAFFERTY, A. MALINOWSKA and D. PELTA

Queensway Surgery, 75 Queensway, Southend-on-Sea SS1 2AB, UK
Correspondence to: Mr P. M. Lafferty

Background Given the generally accepted poor outcome of inguinal hernia repair when using nylon darn, and the recent interest in low-tension mesh repair, an attempt was made to demonstrate the feasibility, outcome and patient perception of providing Lichtenstein inguinal hernia repair, using local anaesthesia, wholly within the primary healthcare sector.

Methods A prospective study reviewed clinical outcome and patient perception in 100 adults referred with inguinal hernia only. No selection was made regarding age, sex, American Society of Anesthesiologists status or previous repairs. Recurrence, pain, infection, return to full function and associated complications were assessed at 24 h, 1 and 6 weeks, and 1 year. Local Community Health Councils assessed patient perception.

Results In the first 100 patients (age range 21–83 (mean(s.d.) 60(14·7)) years; 58 of employable age; 92 men; ten recurrent hernias), no recurrences have occurred at 1 year. Infection rate was 3 per cent. Pain was maximal in the first 24–48 h (median visual analogue scale 5, range 0–10) and reduced rapidly (median 1) at 1 week. Mean time to return to work or full normal activity was 8 days. Some 85 operations were performed within 1 month of diagnosis. In all, 86 patients returned the patient satisfaction questionnaire and 98 per cent of these were 'very pleased' with the service.

Conclusion In highly motivated primary healthcare centres, inguinal hernia repair can be undertaken effectively, providing high patient satisfaction, minimal complications and low recurrence rates using the Lichtenstein technique.

In the early 1990s, the UK Department of Health commissioned a Royal College of Surgeons' working party to review hernia repair nationally. This identified groin hernia as 'one of a number of surgical interventions that accounted for the majority of long wait cases on waiting lists, for which there was a wide range of clinical practice and considerable variation in outcome'. It further concluded that, whilst fewer than 8 per cent of National Health Service (NHS) hernia repairs are performed as day cases, up to 30 per cent of elective hernioplasties could be so performed. In addition, the report emphasized that day surgery is cost effective, and that the establishment of recognized specialist centres could improve overall outcome[1].

Hernia repair has, until now, been the domain of the hospital sector, where traditional darn techniques have been associated with recurrence rates of up to 15 per cent, a hospital stay of a few days, significant postoperative pain and the prospect of return to normal function delayed for 6 weeks. General anaesthesia, with its own complications, is still used invariably in most NHS hospitals[1].

The Audit Commission of 1990 confirmed the economic benefits of day surgery[2]. More recent reports have shown the overall benefits to the patient of both mesh repair and the use of local anaesthesia[3]; however, to date, the role of the primary healthcare sector in providing daycare facilities has not been investigated.

The Lichtenstein Institute has published many reports outlining the use of polypropylene mesh in the repair of groin hernia[4–8]. Its conclusions were that, in conjunction with the 'tension-free' hernia repair, polypropylene mesh has the property of reinforcing abdominal wall hernias without significant risk of rejection, infection or seroma formation, by incorporation into body tissue by rapid fibrinous fixation[5]. A recurrence rate of 0·13 per cent at 5 years was reported using the Lichtenstein technique under local anaesthesia[6]. The technique allows for immediate postoperative ambulation, is well tolerated by the majority of patients, permits an early return to gainful employment (between 2 and 10 days)[7] and, in the present authors' opinion, is best suited to a dedicated primary healthcare setting.

The formal Lichtenstein repair was adopted by the authors, using local anaesthesia and polypropylene mesh (Marlex; Bard UK, Crawley, UK), and experience with this technique in the primary healthcare sector is reported.

Patients and methods

Study location

The health centre operates wholly within the NHS as a primary healthcare–general practice facility. It has a fully equipped operating suite, dedicated nursing personnel, and consulting and postoperative recovery rooms. From June 1994, an unpublished feasibility study of hernia repair with local anaesthetic was undertaken with visiting surgeons from the British Hernia Centre in London. Forty unilateral repairs were completed without complication. A prospective study was subsequently proposed using the services of a full-time surgically qualified partner of the practice (P.M.L.). Training and accreditation were gained by visits to the Lichtenstein Institute in Los Angeles and the London Hernia Clinic.

Protocol

The service was offered to all local NHS general practitioners, who would normally refer patients to established hospitals. At first appointment the need was assessed and the operation explained in full by the surgeon. Only patients with fully

Paper accepted 29 October 1997

reducible hernias were accepted for the study. Verbal and written instructions were given, together with an opportunity to view a video recording explaining the procedure. Informed consent, blood and urine specimens were obtained and a date for operation was given. A named 24-h carer (usually a family member) was recorded and a relationship was established on a first-name basis. The groin area was shaved 24 h before operation and the patient was asked to starve from food for at least 4 h, and from fluids for 1 h, before operation.

On the day of operation, the patient was met by the receptionist, surgeon and scrub-nurse assistant. A full-time consultant anaesthetist was employed on an 'outreach' clinic basis on the day of operation to assess the patient, obtain intravenous access and continue full monitoring with pulse oximeter, electrocardiography, blood pressure and pulse readings throughout the procedure. Full resuscitation equipment and trained staff were available at all times. Immediate access to a surgical bed in a local acute hospital was available, should the need arise, as part of the study protocol.

Before operation suppositories of diclofenac 100 mg (Ciba, Horsham, UK) and prochlorperazine 25 mg (Rhone-Poulenc Rorer, Eastbourne, UK) were given, the incision was marked and the patient was taken to the operating table. Intravenous midazolam (Roche, Welwyn Garden City, UK) and fentanyl (Janssen-Cilag, High Wycombe, UK) were administered to procure light sedation. Continuous oxygen was given via nasal cannulas and the patient was further relaxed by listening to music through a head-set. Local anaesthesia was achieved following the protocol described by Amid and colleagues[8], and the operation was performed following the Lichtenstein protocol[6]. Digital examination of the femoral canal was made in all cases to exclude the presence of femoral hernia, which, if found, was repaired.

Postoperative observations continued for 3 h until the patient was able to eat and drink freely, walk painlessly and unaided, and had passed urine. Visual analogue scale pain assessments were recorded at 1 and 2 h by nurse and patient independently[9]. Patients were asked to make a mark, appropriate to the pain, on a linear 10-cm scale where 0 represents no pain and 10 is agony.

Postoperative management

Patients were advised to rest for a period of 24 h after which graduated exercise commenced. Warm baths were encouraged to ease wound discomfort and help soak off the covering dressing. Discharge medication included one 100-mg diclofenac suppository to be taken on the first night if required. Pain relief was otherwise provided as Co-dydramol (Sanofi Winthrop, Guildford, UK) and Ibuprofen (Brufen 400 mg; Knoll, Nottingham, UK) (one or two tablets, 4–6 hourly) as required. Three 24-h contact mobile telephone numbers were given to the patient: those of the surgeon, scrub-nurse assistant and health centre. Comprehensive written instructions were given to the patient and to the named carer, who were contacted at 24 h by the surgeon or scrub-nurse assistant. During the first week, the patient was asked to record daily the number of tablets taken and visual analogue pain score. At 1 week, wound assessment and complications were recorded, the subcuticular suture was removed and the patient was given an anonymized questionnaire, devised by the Community Health Council (CHC) to assess patient satisfaction. The CHC is a recognized, official, patients' advocate group. The questionnaires were completed independently at the patient's home and returned directly to the CHC offices by stamped addressed envelope, where they were appraised by a medical epidemiologist. Patients were also seen at 6 weeks and at 1 year, when similar data were collected.

Results

The results of the first 100 consecutive inguinal hernia repairs performed from September 1995 to June 1996 are presented. Two additional patients were referred to local hospitals and were not included in the study, one with a history of reaction to local anaesthetic and one who was unable to give the name of an appointed 24-h carer. *Table 1* summarizes characteristics of the 100 patients. *Table 2* gives details of the operative and anaesthetic techniques. Two patients had orchidectomy as an additional planned procedure: one was a 43-year-old man who presented with a small undescended testis, palpable at the internal ring, in association with an indirect hernia sac; the other, aged 76 years, presented with a second recurrence and orchidectomy was considered expedient. A Jaboulay procedure was performed in one patient with a concurrent primary hydrocele. No femoral hernia was found in this study.

*Values are mean (range)

In the postoperative observation period, only three patients recorded a score of 1 (minimal pain) on the visual analogue pain scale at either 1 or 2 h. All other patients recorded zero pain on the scale. One patient experienced paraesthesia in an L1–3 distribution, representing a partial femoral nerve block, for a period of 6 h; there were no lasting effects. All patients left the department at 3 h, pain free, fully mobile and satisfied with the procedure. The facility of immediate access to a hospital surgical bed was not used. At 24 h all patients were contacted; only two home visits were undertaken, by the surgeon who offered advice only. All patients returned for appointments at 1 and 6 weeks; 85 have attended the yearly assessment so far. *Fig. 1* shows the median and interquartile range pain scores recorded by patients using the 10-cm 0–10 visual analogue scale for up to 6 weeks. Postoperative nausea and vomiting did not occur, and there were no recorded instances of cardiovascular, respiratory, circulatory or obstructive urinary complications. Other complications are shown in *Table 3*. No complications were recorded at 1 year (85 patients).

Patient perception survey

The results of this survey have been published in detail elsewhere[10]. Eighty-six patients returned the patient perception questionnaire (*Tables 4* and *5*). Of these, 67 (78 per cent) offered individualized written comments; 84 patients (98 per cent) were 'very satisfied' with the service overall. Mean(s.d.) time to return to work, or normal function, as perceived by the patients, was 8(6·1) (range 1–25) days.

Discussion

It is generally agreed that all indirect and symptomatic groin hernias should be repaired[1]. In the UK inguinal hernia represents 6 per cent of all surgical admissions, 8 per cent of all general surgical operations and occupies 5 per cent of all general surgical beds. Furthermore, 18 per cent of general surgical waiting lists comprise elective hernia repair[1]. In total, more than 80 000 hernias are repaired annually in the UK[1]. Given that these figures are based on primary referral figures, the true prevalence of hernia disease is almost certainly higher, a fact supported by 40 000 trusses being prescribed annually[11]. Recurrence rates of over 10 per cent outside dedicated centres have been suggested, perhaps reflecting non-standardization of operative technique[12].

The Lichtenstein Institute in Los Angeles, the Shouldice clinic in Toronto and the London Hernia Clinic have introduced the prospect of day-case hernia repair associated with little postoperative pain, recurrence rates of less than 1 per cent and a return to normal function within days. Day-case and short-stay hernia repair in hospital facilities have become more widespread[3] in the 1990s, but the authors are not aware of any report of day-case hernia repair carried out in the primary healthcare sector.

This study has indicated that the present-day 'gold standards' can be reproduced safely and effectively in a dedicated, and highly motivated, primary healthcare centre. Such centres could ease the workload of acute general hospitals in the future and provide a programme of postgraduate teaching for surgeons and anaesthetists in training, thereby ensuring a reproducible standard of both care and outcome.

An attempt was made to compare patient satisfaction in the present patients and those operated on at an existing day-case facility in a local acute hospital, using the same CHC questionnaires. However, the low return rate of questionnaires from patients using the acute hospital ($n = 13$) rendered comparison futile.

While it is clear that not all general or family practices have the expertise or facilities to establish such centres, it may be anticipated that, in keeping with the current political emphasis on shift from secondary to primary care, coupled with the probable cost savings, similar specialist primary healthcare units will develop outreach clinics from local acute hospitals.

Background This study investigated the efficacy of local anaesthetic wound perfusion following day-case inguinal hernia repair.

Methods Seventy-two patients entered a randomized controlled trial with three patient groups: group 1, pump containing bupivacaine; group 2, pump containing normal saline; and group 3, control group without a pump. All patients had a Lichtenstein hernia repair together with ilioinguinal and iliohypogastric nerve blocks and were prescribed oral analgesia. Postoperative pain was assessed over 5 days using a visual analogue scale.

Results Patients who had a local anaesthetic infusion had significantly less pain than either the placebo or control groups. This was greatest during the first 48 h (day 1, $P = 0{\cdot}028$ and 0·011 respectively; day 2, $P = 0{\cdot}012$ and 0·037 respectively).

Conclusion A portable infusion pump for the delivery of local anaesthetic reduced pain after day-case inguinal hernia repair.

Day surgery is increasing in the UK; it is predicted that it will account for up to 50 per cent of all surgical procedures performed in the next decade[1,2]. Postoperative pain is a major factor which reduces its acceptability to patients[3]. After day-case inguinal hernia repair 10 per cent of patients have severe postoperative pain requiring the services of a general practitioner (GP) to administer intramuscular opiates[4]. This can be reduced by the use of oral opiates, and pre-emptive and postoperative blockade with locoregional anaesthesia[5–8]. Oral opiates may cause nausea unacceptable to some patients[9]. Locoregional anaesthesia is effective[5,7,8] but is limited in duration of action, even when using long-acting agents such as bupivacaine[7]. Continuous infusion of local anaesthetic into a surgical wound can reduce postoperative opiate requirements[10–12]. Until recently there was not a delivery system suitable for use in day-case surgery.

The authors investigated the use of an infusion pump for the delivery of local anaesthetic for day-case hernia repair.

Patients and methods

Seventy-two consecutive patients undergoing standard unilateral inguinal hernia repair as a day case were included in the trial. Informed consent, as approved by the local ethics committee, was obtained in each case. Each patient was randomized to one of three groups: group 1, pump containing bupivacaine; group 2, pump containing normal saline; and group 3, control group without a pump. Group 3 was included to demonstrate the size of the placebo effect and to exclude the possibility of a negative effect of the placebo.

A Lichtenstein hernia repair[13] was used in every case. Standard sutures were 2/0 polypropylene to sew in the polypropylene mesh, 1/0 polyglactin to close the external oblique aponeurosis and 3/0 subcuticular polydioxanone for skin. Surgery was carried out under general anaesthesia with additional ilioinguinal and iliohypogastric nerve blocks performed before the skin incision using 0·5 per cent bupivacaine 10 ml in every patient. The wound catheter (16-G epidural catheter) was inserted under direct vision under the external oblique aponeurosis before closure and brought out through a separate stab wound laterally. At the end of the procedure the wound was dressed and the pump connected to the wound catheter.

The pump, a Baxter Daymate Elastermeric infusion device (Baxter Healthcare, Thetford, UK) (*Fig. 1*), delivered 2 ml/h and was filled with 100 ml of either normal saline or 0·5 per cent bupivacaine in accordance with a randomization envelope, hence providing an infusion for 50 h. The surgeons, patient and liaison nurse visiting the patient at home remained blinded to the randomization until the end of the trial.

All patients were prescribed oral analgesia with Aspav (Hoechst Marion Roussel, Uxbridge, UK) which they were instructed to take every 4–6 h, to a maximum of eight tablets every 24 h. If necessary, opiates were given in the recovery area or by the GP and their use was recorded.

A liaison nurse visited the patient at home, approximately 48 h after the operation (routine practice) and, as well as her usual checks, removed the pump and wound catheter.

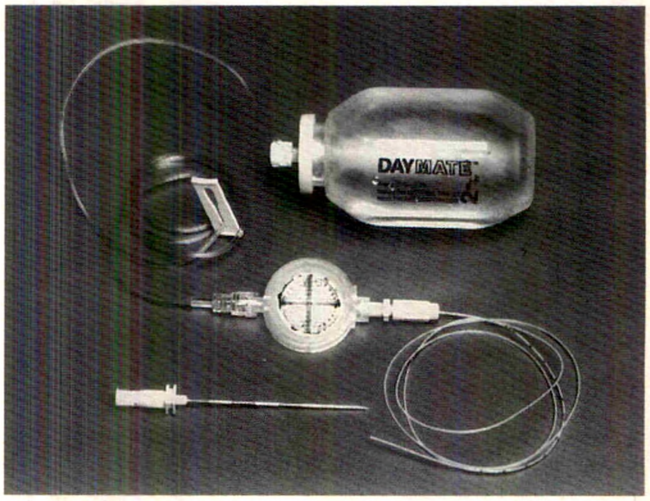

Fig. 1 Baxter device primed with local anaesthetic and attached to the wound catheter. Also shows the trocar used to bring the catheter out through the skin and the bacterial filter

Paper accepted 3 September 1997

Patients were asked to complete a questionnaire recording the pain they had felt over the previous 24 h for each of the 5 days following operation. This was recorded on a visual analogue scale (VAS). Patients were also asked to record additional analgesics used including any injections given by an emergency doctor.

All patients were reviewed in the outpatient department 4 weeks after surgery and the wounds inspected.

Analysis of the results was made with the Mann–Whitney *U* test using Minitab for Windows (Microsoft) version 10.2. $P<0{\cdot}05$ was considered significant.

Results

The patient groups were comparable in age and sex (*Table 1*).

Infusion of bupivacaine for 50 h after operation significantly reduced the VAS score recorded by patients when compared with placebo and control groups (day 1, $P=0{\cdot}028$ and 0·011 respectively; day 2, $P=0{\cdot}012$ and 0·037 respectively) (*Fig. 2*). Over the remaining 3 days recorded pain differences between the groups slowly equilibrated. There was no rebound increase in pain at the end of the bupivacaine infusion.

There was no significant difference in the analgesic requirement between the groups (*Table 2*). Four patients developed a wound infection (one in group 1, one in group 2 and two in group 3). No patient developed nerve entrapment or significant hypoaesthesia and all wounds were well healed at the 4-week review.

Table 1 Age and sex distribution

Group	No. of patients	Mean (range) (years)	Sex ratio (M : F)
1	25	53 (17–83)	23 : 2
2	24	58 (21–78)	22 : 2
3	23	56 (23–81)	23 : 0

Discussion

The Baxter Daymate Elastomeric Infusion Device is a portable, disposable, low-cost perfusion pump that delivers fluid reliably at a fixed rate. The pump provides postoperative analgesia safely and at a level equivalent to that of oral opiates without the associated nausea[9]. In the present study the infusion of bupivacaine for 50 h after operation resulted in significantly less pain than in either the placebo or the control group as measured with a standardized 10-cm VAS. This effect seemed to be prolonged after the end of the infusion possibly because of prevention of sensitization of the central nervous system. This effect may be potentiated by an increase in the duration of the neuronal blockade[14,15]. These results were obtained in patients having the hernia repair believed to produce the least postoperative pain[13] together with ilioinguinal and iliohypogastric nerve blocks[5,7]. The clinical advantage of this method for day-case surgery is the ability to provide adequate analgesia safely with regard to the peak plasma levels of bupivacaine[9,16]. There was no increase in the incidence of wound infection and no patient in the study had a deep wound infection.

The position of the catheter under the aponeurosis is a more effective site than subcutaneously[17]. No patient suffered an iatrogenic femoral nerve block. There was no significant difference in the additional analgesic use between the groups. Of the 72 patients in the study, six required additional parenteral analgesia, but only one after bupivacaine infusion.

The use of a pump for local anaesthetic wound perfusion after inguinal hernia repair is an effective method of reducing postoperative pain and is suitable for day surgery.

Acknowledgements

The authors thank Baxter Healthcare for supplying the Daymate pumps used in this trial.

Correspondence to: Mr R. R. Dozois, Division of Colon and Rectal Surgery, Mayo Clinic, 200 First Street SW, Rochester, Minnesota 55905, USA

Aim The purpose of the study was to determine the risk of postoperative complications and the functional outcome after a hand-sewn ileal pouch–anal anastomosis (IPAA) for ulcerative colitis using a single J-shaped pouch design.

Methods Preoperative function, operative morbidity and long-term functional outcome were assessed prospectively in 1310 patients who underwent IPAA between 1981 and 1994 for ulcerative colitis.

Results Three patients died after operation. Postoperative pelvic sepsis rates decreased from 7 per cent in 1981–1985 to 3 per cent in 1991–1994 ($P = 0·02$). After mean follow-up of 6·5 (range 2–15) years, the mean number of stools was 5 per day and 1 per night. Frequent daytime and night-time incontinence occurred in 7 and 12 per cent of patients respectively, and did not change over a 10-year period. The cumulative probability of suffering at least one episode of 'clinical' pouchitis was 18 and 48 per cent at 1 and 10 years and the cumulative probability of pouch failure at 1 and 10 years was 2 and 9 per cent respectively.

Conclusion These results indicate that increased experience decreases the risk of pouch-related complications and that with time the functional results remain stable, but the failure rate increases.

Ileal pouch–anal anastomosis (IPAA) for chronic ulcerative colitis was first described in 1978[1], and has since become a well established procedure. However, it is a technically demanding operation which can be associated with serious complications, especially sepsis, which may have a detrimental effect on outcome[2,3]. It is thus important to know whether the incidence of major complications, noted in previous publications to affect up to 54 per cent of patients[4–17], decreases with increasing experience. Early bowel function following IPAA has been demonstrated to be acceptable[4–18], but it is uncertain whether function changes significantly over prolonged follow-up. Similarly, the incidence of long-term complications of IPAA, particularly pouchitis and small bowel obstruction during extended follow-up, is not known. Early pouch failure, with excision of the pouch or creation of a permanent ileostomy, is generally uncommon, although published rates have varied between 2 and 22 per cent[4–10,12–14,16–18]. The incidence and causes of late pouch failure remain to be determined. Finally, many reports on the IPAA include various configurations of reservoirs with or without 'mucosectomy' performed in patients afflicted by different diseases, all of which may influence outcome.

The objective of this study was to examine the long-term results of the J-shaped pouch for chronic ulcerative colitis only. Specific emphasis has been placed on the effect of increasing surgical experience on postoperative morbidity, the changes in bowel function with prolonged follow-up and the long-term incidence of pouchitis and late pouch failure.

Paper accepted 1 October 1997

Patients and methods

Between January 1981 and December 1994, 1608 patients underwent IPAA in this centre, 1410 (87 per cent) of which were for chronic ulcerative colitis. Of these 1410 patients, 54 had coexisting cancer and were excluded from further analysis. The type of pouch constructed in the remaining 1356 patients was J shaped in 1310 (97 per cent), S shaped in 27 (2 per cent), W shaped in 17 (1 per cent) and lateral–lateral in two. Most patients had diverting ileostomies constructed at the original pouch procedure, but 56 (4 per cent) did not.

All patients were followed by a nurse research assistant who first collected preoperative data and then contacted the patients by telephone 6 months after ileostomy closure, and then yearly by written and/or telephone questionnaire. Surgeons did not contribute to data collection. Data accrued included details of preoperative bowel, urinary and sexual function, operative morbidity and mortality, postoperative stool frequency, continence data, the ability to distinguish gas from stool, medication requirements, episodes of pouchitis and pouch failure. For the purpose of IPAA follow-up, daytime and night-time faecal incontinence was characterized as nil, occasional spotting (two or fewer episodes per week and no interruption of daily activities), or frequent (more than two per week with interruption of daily activities) or gross faecal soiling. Pouchitis was identified clinically by the sudden onset of frequent, watery, sometimes bloody, stools with urgency, often associated with abdominal cramping, malaise and fever. An episode of pouchitis was considered to have occurred if a patient suffered the above symptoms for more than 2 days, and symptoms were relieved within 48 h by metronidazole or other antibiotics. Pouch failure indicated that the pouch was excised or a diverting ileostomy was required for more than 1 year.

The mean age of patients at IPAA was 33 (range 5–65) years. There were 689 male and 621 female patients. Before operation, mean stool frequency per day was 10 (range 1–35) and 7 per cent of patients had episodes of faecal incontinence; 14 per cent did not participate in any form of sexual activity and a further 73 per cent reported reduced sexual activity.

The operative technique of IPAA has been described previously[8]. A diverting ileostomy was performed in 96 per cent of patients. The ileostomy was closed a mean of 97 days after operation. Three hundred patients had completed follow-up at 1, 5 and 10 years after surgery.

Statistical analysis

Proportions of events were compared in two groups with the χ^2 or Fisher's exact test. Comparison of ordinal variables, such as daytime and night-time number of stools, were compared in two groups with the Wilcoxon rank sum test. Changes over time within an individual in ordinal variables were assessed with the Wilcoxon rank sum test. The association of ordinal variables with one another, or of ordinals with continuous variables, was assessed with Spearman's rank correlation coefficient. The cumulative probabilities of pouchitis, pouch failure and small bowel obstruction were estimated by means of the Kaplan–Meier survivorship method. Results are expressed as mean (range).

Results

Postoperative morbidity and mortality

Three patients died after operation. One patient died from a massive pulmonary embolism 2 weeks after discharge from hospital, another died several weeks after suffering complications of a perforated gastric ulcer, and one patient died from a subarachnoid haemorrhage.

The overall complication rate within the immediate postoperative period was 19 per cent. Pelvic sepsis occurred in 74 patients (6 per cent). Seventy-three of these patients experienced sepsis as a result of the pouch procedure whereas one did so because of a perforated gastric ulcer. Twenty-seven patients were treated by antibiotics alone ($n = 11$) or in combination with computed tomographic drainage ($n = 16$), while 46 patients (63 per cent) required operative intervention. Abdominal wound infection occurred in 39 patients (3 per cent). Some 195 patients (15 per cent) developed a perioperative episode of small bowel obstruction, with 47 requiring laparotomy.

Fifteen patients (1 per cent) never had the ileostomy closed. Six of these patients preferred to have the stoma for personal reasons. Of the remaining nine patients, reasons for failure to close the ileostomy were pelvic abscess ($n = 5$), poor anal squeeze effort ($n = 1$), peritonitis ($n = 1$), pouchitis ($n = 1$) and unknown reasons ($n = 1$).

With increasing experience the incidence of postoperative sepsis decreased significantly, from 7 per cent in 1981–1985 to 3 per cent in 1991–1994 ($P = 0\cdot02$). During the same time periods, wound infection rates were similar at 2 and 1 per cent respectively.

Stool frequency

At discharge from hospital the patients had a mean stool frequency of 6 (range 1–17) per day and 1 (range 0–9) per night. Seventy-nine per cent were always continent, 19 per cent had occasional incontinence and 2 per cent suffered frequent incontinence. Thirty per cent were discharged on Lomotil (Searle, Chicago, Illinois, USA), 19 per cent on loperamide and 4 per cent on a bulk-forming agent.

After a mean follow-up of 6·5 (range 2–15) years the mean number of stools per day was 5 (range 1–20) and the number of stools per night was 1 (0–15). The number of stools per 24 h was 6 (1–20), which was significantly less than before operation (10 (1–35) per 24 h) ($P < 0\cdot0001$).

Continence status

Fifty-four per cent of patients had normal continence during the day, 39 per cent had occasional mucous spotting and 7 per cent suffered frequent episodes of incontinence; 17 per cent wore a protective pad. Thirty per cent never leaked at night, 59 per cent had occasional mucous spotting and 12 per cent suffered frequent incontinence. There was no significant difference in these parameters between male and female patients, except that women were fully continent at night more often than men (45 *versus* 37 per cent).

Statistically, there was a significant correlation between preoperative stool frequency and stool frequency at last follow-up ($P = 0\cdot0001$). No significant correlation was noted between preoperative and postoperative incontinence ($P = 0\cdot84$).

To assess the change in bowel function with prolonged follow-up, the 300 patients who had follow-up at 1, 5 and 10 years were analysed separately. The number of stools remained the same at 1 and 10 years (mean daytime frequency 5·7; mean nocturnal frequency 1·2). Overall, bowel function was stable, with no significant change in continence from the 5-year follow-up to 10 years (*Tables 1* and *2*) Perineal skin irritation did not change in incidence with long-term follow-up for the entire group, and the need to take antidiarrhoeal medication decreased, but not significantly (*Table 3*).

Table 1 Incidence of daytime incontinence in 300 patients followed for 1, 5 and 10 years

Incontinence	1 year	5 years	10 years
None	80	76	73
Occasional	19	22	25
Frequent	1	2	2

Values are percentages

Table 2 Incidence of nocturnal incontinence in 300 patients followed for 1, 5 and 10 years

Incontinence	1 year	5 years	10 years
None	59	59	48
Occasional	49	38	44
Frequent	2	3	8*

Values are percentages. *$P < 0\cdot05$ *versus* 1 year (Wilcoxon rank sum test)

Table 3 Functional outcome in 300 patients at 1, 5 and 10 years

	1 year	5 years	10 years
Wears a pad	25	22	15
Takes antidiarrhoeal medication	48	37	39
Perineal irritation	56	44	51
Can distinguish gas from stool	70*	82	87
Sexual dysfunction	14*	7	8

Values are percentages. *$P < 0\cdot05$ (1 year *versus* 5 and 10 years, Wilcoxon rank sum test)

Sexual dysfunction

At last follow-up, ten men (1 per cent) reported impotence and 13 (2 per cent) reported retrograde/lack of ejaculation that was not present before operation. In addition, 21 women (3 per cent) reported dyspareunia and 18 (3 per cent) reported fear of leakage of stool during intercourse. It was apparent that the number of patients who reported sexual dysfunction after IPAA improved as compared to 1 year (*Table 3*).

Long-term small bowel obstruction

Following closure of the ileostomy 202 patients (15 per cent) developed at least one episode of small bowel obstruction. Of these, 93 (46 per cent) were treated conservatively. The cumulative probability of developing small bowel obstruction 5 years after ileostomy closure was 14 per cent, whereas at 10 years it was 22 per cent.

Pouchitis

In all, 559 patients suffered at least one episode of pouchitis. The cumulative risk of suffering at least one episode was 18 per cent at 1 year after IPAA and 48 per cent at 10 years. Some 394 of the 559 patients who had at least one attack of pouchitis suffered a second episode. The cumulative probability of suffering a second episode after an initial attack within 2 years of IPAA was 64 per cent. Age, sex and postoperative sepsis did not influence the risk of developing pouchitis.

Pouch failure

A total of 134 patients (10 per cent) were considered to have suffered pouch failure at last follow-up (84 pouch excisions and 50 defunctioning ileostomies). The overall pouch failure rate was dependent on the length of follow-up. The cumulative probability of pouch failure was 2, 5 and 9 per cent at 1, 5 and 10 years respectively after IPAA.

Three pouches were excised within 30 days of surgery for ischaemia. Chronic sepsis was the commonest cause of pouch failure within 2 years of surgery ($n = 40$) and generally presented as recurrent pelvic abscesses, with or without fistulas. The symptoms of poor functional outcome, the second most common cause of pouch failure ($n = 26$), were usually increased stool frequency with incontinence and perineal irritation. No pouch has been excised for poor function since 1989. Twenty-one patients (2 per cent) had rediversion after initial closure of the stoma. Poor function ($n = 6$), pelvic sepsis ($n = 6$), pouch fistula ($n = 4$), Crohn's disease ($n = 3$), anastomotic stricture ($n = 1$) and pouchitis ($n = 1$) were the principal reasons.

Discussion

This study indicates that 91 per cent of patients followed for 10 years had a functioning IPAA. Among these, mean stool frequency was 6 per 24 h, and about 90 per cent of patients had either no incontinence or rare spotting. Bowel function during this prolonged follow-up has been relatively stable. Postoperative morbidity has been acceptably low. It is evident from this study that the IPAA remains a viable and appropriate surgical procedure in the treatment of chronic ulcerative colitis.

The incidence of pelvic sepsis following IPAA in published series has varied widely, from 0 to 24 per cent[4–17], and it is likely that a number of factors, including operative technique, patient selection, the proportion of patients with familial adenomatous polyposis and the methods of diagnosing sepsis may explain these differences. More recent and larger series have noted pelvic sepsis in 5–14 per cent of patients[11,16,17]. The present study shows that with increasing experience significant decrease in pelvic sepsis occurs. Patients who require reoperation for pelvic sepsis are at increased risk of pouch excision[2,3]. While a temporary ileostomy does not protect the patient against sepsis and may be associated with significant morbidity[19], the authors still establish a temporary ileostomy in most patients in an attempt to decrease the incidence and consequences of pelvic sepsis. A number of authors[20–24] and a recent randomized trial[25] have indicated that the risk of pelvic sepsis may not be increased by avoiding a temporary ileostomy.

Previous shorter-term analyses of IPAA have demonstrated that bowel function generally is acceptable[4–18]. Importantly, the present analysis has demonstrated that postoperative bowel function remains stable over a 10-year follow-up period for most patients.

The cause of pouchitis is unknown, although it has been shown to be more common in chronic ulcerative colitis than in familial adenomatous polyposis[26], and is more common in patients with extraintestinal manifestations of ulcerative colitis[27], especially primary sclerosing cholangitis[28]. The present analysis demonstrates that the number of patients affected by pouchitis continues to increase with prolonged follow-up. Moreover, it would appear that those who suffer one episode of pouchitis within 2 years of IPAA are likely to have further episodes, whereas those who do not develop pouchitis within the first 2 years are at decreased risk of recurrent pouchitis. In this study the clinical diagnosis of pouchitis was used and it is conceivable that this led to overdiagnosis. Although endoscopic and histological assessment may be helpful in confirming pouchitis, they may also confuse the issue. A pouchitis activity index which combines clinical, endoscopic and histological findings might more accurately predict the true risk of pouchitis. Fortunately, pouchitis typically responds favourably to antibiotic therapy, and in this series was the cause of pouch failure in only three patients.

Small bowel obstruction is observed frequently before ileostomy closure, and remains a potential problem after closure. The proportion of patients suffering small bowel obstruction following IPAA varies between 12 and 24 per cent[29], and it is likely that one of the major determinants of this is the length of follow-up. The total number of patients suffering an episode of small bowel obstruction following IPAA continues to increase significantly for up to 10 years after operation, as might be anticipated after any major abdominal procedure.

Sexual dysfunction following IPAA is uncommon but disturbing. The present study takes into account preoperative sexual dysfunction and indicates that sexual activity improves substantially after long-term follow-up.

Pouch failure increases slightly with prolonged follow-up, and it is preferable to analyse pouch failure as a cumulative risk. While the authors consider a failure rate of 9 per cent at 10 years to be acceptable, especially in light of the alternative surgical procedures available, future patterns of failure will need to be observed. In this series, immediate pouch excision was rare (three of 1310 patients). Pouch failure requiring excision within 2 years was secondary to sepsis and fistula formation whereas pouchitis and Crohn's disease were the primary causes of pouch failure more than 2 years after surgery. The predominant causes of pouch failure in this study, chronic pelvic sepsis, poor functional outcome and Crohn's disease, have also been the foremost aetiologies in two other series[14,16]. Pouch infarction[17] is a most uncommon cause for pouch excision in the authors' experience.

In summary, detailed long-term analysis of 1310 patients with chronic ulcerative colitis undergoing IPAA with a J-shaped reservoir shows that the incidence of postoperative pelvic sepsis decreases significantly with increasing experience. The proportion of patients suffering pouchitis, small bowel obstruction and pouch failure increased with increasing length of follow-up, whereas postoperative sexual dysfunction improved with time. These data support the continued use of IPAA in most patients requiring proctocolectomy for chronic ulcerative colitis.

Background Construction of an ileal faecal or urinary reservoir profoundly alters ileal luminal ecology and availability of mucosal metabolic substrates. The aims of this study were to measure mucosal metabolic flux of butyrate and glutamine in histologically normal (control) ileum and to determine the effect of reservoir construction on metabolic fluxes in patients with ileal pouch–anal anastomosis and ileocystoplasty.

Methods Endoscopic biopsy samples were obtained from normal ileum ($n = 10$), ileum of patients with ulcerative colitis ($n = 10$), ileal pouch–anal anastomosis ($n = 7$), ileocystoplasty ($n = 7$) and ileal conduit ($n = 7$). Using a closed microculture technique, biopsy utilization of ^{14}C-labelled butyrate and glutamine was measured as [^{14}C]carbon dioxide production. Biopsy DNA content was measured and [^{14}C]carbon dioxide evolution expressed as picomoles [^{14}C]carbon dioxide per microgram DNA per hour.

Results The metabolic flux of both butyrate and glutamine was reduced in ileal pouch mucosa compared with that of ileal mucosa in patients with ulcerative colitis. In contrast, the metabolic flux of buyrate alone was reduced in ileal mucosa from ileocystoplasty and ileal conduit compared with that in normal ileal mucosa, while the metabolic flux of glutamine remained unchanged.

Conclusion Ileal mucosal metabolic fluxes measured *in vitro* are altered by changing luminal ecology *in vivo*. These changes may affect the health and mucosal integrity of ileum used to construct these reservoirs.

Intestinal mucosal cells metabolize both circulating and luminal metabolic substrates. Circulating glutamine and ketone bodies are the preferred respiratory fuels of ileal mucosa[1], while luminal short-chain fatty acids (SCFAs), the end-product of bacterial fermentation of dietary carbohydrate, provide the principal substrates for oxidation by colonic mucosal cells[2]. Construction of either a faecal or urinary reservoir from distal ileum has profound effects on luminal ecology[3,4]. Changes in luminal metabolic substrate availability may disrupt the metabolic pathways of otherwise healthy mucosa. In the case of ileal pouch–anal anastomosis the healthy equilibrium of ileal ecology is disturbed, a change which may have long-term metabolic and morphological consequences. These changes have been associated with the development of pouchitis[5] which primarily occurs in patients with antecedent ulcerative colitis. The exact aetiology of pouchitis is unknown but alterations in luminal SCFA availability have been implicated in its pathogenesis[6–8]. By contrast, ileal mucosa used to construct a urinary reservoir is exposed to a very different ecology, with complete absence of luminal SCFAs. Changes in mucosal morphology occur soon after reservoir construction[9,10] which may be important for long-term stability of transposed ileal mucosa.

The aims of this study were to determine metabolic substrate utilization in healthy ileal mucosa and to compare this with ileal mucosal metabolism in an ileostomy, ileal pouch anal (faecal) reservoir, ileal (urinary) conduit and ileocystoplasty.

Patients and methods

Control mucosal biopsies were obtained from the terminal ileum of patients undergoing surgical resection for colonic carcinoma ($n = 10$). Control biopsies were taken at least 5 cm from the macroscopic abnormality and all were subsequently histologically normal. Mucosal biopsies were obtained from the terminal ileum of ten patients, free of backwash ileitis, undergoing total colectomy for ulcerative colitis. Biopsies were also taken from the terminal ileum of patients with an established ileostomy for either colonic carcinoma ($n = 8$) or ulcerative colitis ($n = 8$). Biopsies of ileal faecal reservoir mucosa were taken from patients with antecedent ulcerative colitis ($n = 7$) who had a functioning ileal pouch–anal anastomosis without active pouchitis. Endoscopic biopsy specimens were obtained using a standard flexible endoscopic forceps (Olympus FB 13U; Olympus, Tokyo, Japan) and were taken by a surgeon or gastroenterologist of consultant or senior registrar status. Ileal mucosal biopsies were taken from seven patients with ileocystoplasty reservoirs during routine surveillance cystoscopy and from seven patients with an ileal conduit using a flexible cystoscopy forceps (Olympus FB-195X). All patients were in good health with well functioning reservoirs or stomas at the time of biopsy at least 2 years following operation.

Five biopsy specimens were taken from each patient of which two biopsies were used to measure butyrate metabolism, two to measure glutamine metabolism and one reserved for histological examination. Biopsies for metabolic studies were transported in ice-cold sterile RPMI-1640 cell culture medium without glutamine (Gibco, Uxbridge, UK) and assayed immediately. Biopsies were taken from operative specimens by dissection of

Presented in part to the American Gastroenterological Association in San Francisco, California, USA, May 1996, and published in abstract form as *Gastroenterology* 1996; **110**: A899
Paper accepted 6 November 1997

mucosa into 1-mm^3 pieces using a sterile scalpel before transport and immediate assay. All patients gave written informed consent and the protocol was approved by the ethics committee of the Mater Misericordiae Hospital.

Determination of metabolic flux

The metabolic activity of each biopsy specimen was determined by measuring oxidation of [^{14}C]butyrate or [^{14}]glutamine to [^{14}C]carbon dioxide over a 2-h incubation period[11]. Before assay each biopsy was blotted dry and the wet weight recorded. Each biopsy was then placed in a Prolene (Ethicon, Edinburgh, UK) mesh basket attached to a polypropylene suture and transferred to an individual 20-ml Universal glass bottle (Merck, Poole, UK) containing 2-ml sterile RPMI-1640 cell culture medium supplemented with either sodium butyrate 5 mmol/l (Gibco) or L-glutamine 5 mmol/l (Sigma, Poole, UK). These concentrations of glutamine and butyrate were chosen as they have been shown to be within or slightly above the physiological concentration in the human intestine[12,13]. To determine metabolic conversion of either butyrate or glutamine to carbon dioxide, either 3·7 KBq[1-^{14}C] sodium butyrate (specific activity 1·85 MBq) (New England Nuclear, Dreiech, Germany) or 37 KBq L-[U-^{14}C] glutamine (specific activity 1·85 MBq) (Amersham, UK) was added to each Universal bottle containing a biopsy specimen. Released [^{14}C]carbon dioxide was trapped by reaction with sodium hydroxide-saturated filter paper suspended in an opened Eppendorf tube (Eppendorf, Hamburg, Germany) inside each sealed Universal bottle as described by Chapman *et al.*[14]. The quantity of ^{14}[C]carbon dioxide recovered was then determined by liquid scintillation counting. Mucosal biopsies were recovered and frozen at −80°C. Biopsy DNA content was quantified using the standard fluorescent Hoechst dye assay technique[15,16]. Metabolic fluxes for both butyrate and glutamine were then expressed as pmol [^{14}C]carbon dioxide per microgram DNA per hour and pmol ^{14}[C]carbon dioxide per milligram wet weight per hour.

Statistical analysis

All data are expressed as mean(s.e.m.). Duplicate data from each pair of biopsies were consolidated by taking the mean in each case. Comparisons between study groups were performed by one-way analysis of variance with Bonferroni post hoc adjustment. $P \leq 0{\cdot}05$ was considered significant.

Results

Mucosal metabolism in healthy ileal mucosa

There was no significant difference in either butyrate (*Fig. 1a*) or glutamine (*Fig. 1b*) metabolism between control ileal mucosa and ileal mucosa from patients with ulcerative colitis. Mucosal metabolic flux was greater when butyrate rather than glutamine was the available substrate in control ileum and ileum in ulcerative colitis, with a ratio of 6·7 to 1 in respect of control ileal mucosa and 4·9 to 1 in respect of ileal mucosa in ulcerative colitis (*Table 1*).

Mucosal metabolism in ileostomy mucosa

There was no difference in either butyrate (*Fig. 1a*) or glutamine (*Fig. 1b*) metabolism in ileostomy mucosa from patients with either a previous history of colonic carcinoma or ulcerative colitis and control ileal mucosa. Similarly there was no difference in either butyrate (*Fig. 1a*) or glutamine (*Fig. 1b*) metabolism between ileostomy and ileal mucosa from patients with ulcerative colitis. The ratio of butyrate to glutamine metabolic flux was similar in both ileostomy mucosa and control ileal mucosa (*Table 1*).

Mucosal metabolism in ileal pouch mucosa

A significant reduction in both butyrate (*Fig. 1a*) and glutamine (*Fig. 1b*) metabolism was observed in ileal pouch reservoir mucosa when compared with both ileal mucosa and ileostomy mucosa from patients with ulcerative colitis. Nevertheless, the ratio of metabolic fluxes of butyrate and glutamine was preserved (*Table 1*). When wet weight was used as the denominator for expressing metabolic flux, a reduction in the metabolic fluxes of both butyrate and glutamine was also observed (*Table 2*). The

Ileal pouch ($n = 7$)	4·7(0·3)*	4·4(0·6)*

Values are mean(s.e.m.). *$P \leq 0{\cdot}05$ *versus* normal ileum (analysis of variance)

Metabolism in urinary reservoirs

The metabolic flux of butyrate was reduced in ileal mucosa from ileocystoplasty and ileal conduit compared with that in control ileal mucosa (*Fig. 2a*), while there was no difference in glutamine metabolism between ileal conduit and control ileal mucosa (*Fig. 2b*). There was an increase in glutamine metabolism in ileocystoplasty mucosa but this did not reach statistical significance (*Fig. 2b*).

Histology

Standard light microscopy (haematoxylin and eosin stain) confirmed the presence of intact ileal mucosa in the fifth biopsy taken from each patient. Mucosal morphometry was not performed.

Discussion

In this study the dramatic effects of *in vivo* ileal reservoir construction on mucosal metabolism of butyrate and glutamine, two of the principal metabolic substrates of ileal mucosa, have been demonstrated *in vitro*. The metabolic flux of both butyrate and glutamine, under controlled conditions of substrate availability, is reduced in ileal mucosa following incorporation into an ileal faecal reservoir whereas the metabolic flux of butyrate alone is reduced in ileal conduit and ileocystoplasty mucosa while that of glutamine is preserved. It was found that the metabolic fluxes of butyrate and glutamine are unchanged in the terminal ileum and established ileostomy of patients with ulcerative colitis when compared with those in control ileum and ileostomy performed for bowel cancer, clearly demonstrating the absence of a panenteric disorder of butyrate metabolism in ulcerative colitis.

Luminal faecal stasis alters the ecology of an ileal pouch which in turn is associated with morphological changes in the mucosa with the appearance of villous atrophy, crypt hyperplasia and chronic inflammation, a combination often described as colonic metaplasia[17–19]. Bacteriological studies have shown that faecal concentrations of total anaerobes, as well as the ratio of total anaerobes to total aerobes in ileal pouch reservoirs are increased compared with those of ileostomy effluent and are comparable to those of the colon[4,6,17,20,21]. With this change to a colonic ecology, increased production of SCFAs *in vivo* might be expected as a result of bacterial fermentation. Indeed SCFA concentrations are increased in ileal pouch effluent compared with those in ileostomy effluent[6] and are similar to luminal concentrations in healthy colon[7].

The present findings differ from those of Chapman *et al.*[22] who claimed evidence of colonic-type metabolic adaptation in ileal pouch faecal reservoir mucosa by showing a decrease in mucosal glutamine metabolism but no change in pouch butyrate metabolism. This discrepancy may be explained by the different methods used to express metabolic flux; Chapman *et al.* used biopsy protein content, whereas biopsy DNA content was used as the denominator for expression of metabolic flux in the present study. This was done to improve assay reproducibility[23]. In this study biopsy DNA:wet weight ratio was increased in pouch ileal mucosa compared with that in control ileal mucosa suggesting the presence of metabolically inert inflammatory cells[24]. However, expression of metabolic fluxes is similar if wet weight is employed as the denominator, indicating that the reduction in mucosal metabolism in ileal pouch mucosa is not solely due to an influx of inflammatory cells but may reflect partial villous atrophy and increased crypt cell proliferation[21].

The modified assay technique used in this study was chosen to most closely reflect *in vivo* mucosal metabolism. The technique allows sampling from macroscopically diseased or macroscopically healthy areas of mucosa and does not require a surgical resection as is required for isolated mucosal cell cultures[2,25]. Furthermore, use of endoscopic biopsies opens the possibility of serial metabolic studies, of particular value in the study of pouchitis. However, the metabolic fluxes measured do reflect total biopsy metabolism, and are subject to differences in biopsy thickness, morphological variation and the presence of submucosal and inflammatory cells[24]. Nevertheless, the technique does provide mucosal cells with more physiological *in vitro* exposure to both luminal and submucosal nutrients than isolated cell culture techniques[2,25].

In previous work[22], metabolic fluxes have been determined in incubations containing both butyrate and glutamine, only one of which was radiolabelled. In the present study the metabolic flux of each substrate was measured in isolation. Whether this explains the different finding in ileal pouch mucosa described by Chapman *et al.*[22] is uncertain. It is possible that a relatively high *in vitro* concentration of unlabelled glutamine may alter oxidation of labelled butyrate. While Chapman *et al.* separately measured the metabolic flux of glucose, in neither study was glucose present in the culture medium as it has little effect on the production of carbon dioxide from either butyrate[2] or glutamine[25].

In contrast to the metabolic effects of ileal pouch faecal reservoir construction, the mucosal metabolic flux of butyrate was reduced in both ileocystoplasty and ileal conduit but that of glutamine was maintained in both and possibly increased in ileocystoplasty. The reduction in butyrate metabolism cannot be explained solely by villous atrophy, which is likely to affect the metabolism of both substrates, but probably reflects decreased luminal substrate availability with downregulation of enzymatic pathways involved in butyrate metabolism. A compensatory increase in the metabolic flux of glutamine is possible in ileocystoplasty.

The reduction in butyrate metabolism in ileal urinary reservoirs may have important implications for the morphological stability of the reservoir mucosa as butyrate is known to stabilize colonic mucosa and to act as a differentiating agent in experimental models[26,27]. Metabolic acidosis, which occurs after enteric urinary diversion[28,29], increases exposure of enteric mucosa to ammonia which, in turn, has been shown to induce morphological changes in the epithelium[30]. In the colon SCFA production reduces exposure of mucosa to ammonia through a reduced luminal pH, which increases conversion of ammonia to the less absorbable ammonium. However, this pathway is not available in ileocystoplasty mucosa. With the loss of the cytoprotective effect of butyrate[31] the present data raise concerns that reduced butyrate metabolism in ileocystoplasty and ileal conduit mucosa may render the mucosa more susceptible to proliferation and neoplastic change[32].

A reduction in the metabolic fluxes of butyrate and glutamine in ileal pouch faecal reservoirs performed for ulcerative colitis was observed which was related to changes in luminal ecology and mucosal morphology and not to a panenteric metabolic abnormality. There was a reduction in the metabolic flux of butyrate in ileal urinary reservoirs related to substrate availability or downregulation of enzymatic pathways involved in butyrate metabolism. These changes in mucosal metabolism may have important implications for the health and integrity of mucosa used to construct these reservoirs.

Extrafascial excision of the rectum for rectal cancer

G. L. HILL and M. RAFIQUE

University Department of Surgery, Auckland Hospital, Auckland, New Zealand
Correspondence to: Professor G. L. Hill

Background The fascia propria of the rectum is an upward capsular projection from the superior fascia of the pelvic floor which surrounds the rectum and its mesorectum posteriorly and the fat, blood vessels, nerves and lymphatics in front and laterally. It is postulated that if rectal cancer is contained within the fascia propria and extrafascial excision of the rectum is performed then it would be exceptional for the cancer to recur locally.

Methods A total of 122 consecutive patients with rectal cancer underwent extrafascial excision of the rectum. The operation involved mobilizing the rectum outside its fascia propria and removing not only the rectum and its mesorectum posteriorly but also the fat, blood vessels, nerves and lymphatics in front and laterally. Resection was considered curative unless there were distant metastases or the tumour had involved the resection margins.

Results There was one postoperative death. The cumulative cancer-free survival rate at 5 years was 68 per cent. In 100 patients in whom the operation was considered to be curative, the cumulative cancer-free survival rate was 81 per cent. Eighty-four of these patients were available for a minimum follow-up of 24 (median 73, range 24–193) months. Three (4 per cent) developed local recurrence. In two patients this was at the anastomosis.

Conclusion If the cancer is contained within the fascial tube surrounding the rectum and complete extrafascial excision has been performed, local recurrence will be minimal.

A decade ago a review of the surgical anatomy of the rectum was presented with particular relevance to the technique of rectal excision[1]. Over a period of some years, through literature research and by dissection, a new understanding of the fascia propria of the rectum was gained; it was learned that a gossamer-like membrane surrounds the rectum, enclosing the mesorectum posteriorly and fat, blood vessels, nerves and lymphatics in front and laterally. The fascia propria could be identified at surgery and the rectum mobilized by dissecting outside it, particularly in patients with cancer; it seemed logical that if the rectal cancer was contained within the fascia propria and extrafascial excision had been performed then it would be exceptional, if not impossible, for the cancer to recur locally. Furthermore, the use of the term 'extrafascial excision' would highlight to surgeons and others the vital importance of dissecting in the correct tissue planes in order to avoid recurrent cancer.

Here, the outcome of a consecutive series of patients with rectal cancer in whom the rectum was removed by the extrafascial excision technique is reported.

Patients and methods

The outcome of all patients with rectal cancer personally operated on by one of the authors (G.L.H.) over a 15-year period was studied.

Survival data and the cause of deaths in patients who did not die in hospital were obtained from the New Zealand office of the Registrar of Births, Deaths and Marriages. There was complete follow-up of all patients. Survival was estimated by the method of Kaplan and Meier[2].

Definitions

Operations were considered curative when there was no macroscopic tumour remaining, no distant metastases and the circumferential resection margin (CRM) and distal resection margin were microscopically free of tumour. All other operations were termed 'palliative'.

The lower border of the tumour was measured from the anal verge with a rigid sigmoidoscope with the patient in the left lateral Sims' position. The rectum was divided into lower (0–7 cm), middle (8–11 cm) and upper (12–15 cm) thirds.

The distal margin of clearance was defined as the measured distance from the edge of the tumour at operation in the unstretched rectum. The CRM was identified by inking the fascia propria surrounding the rectum. The CRM was said to be positive when tumour penetrated the margin.

The duration of follow-up was calculated from the date of operation to the date of this review. Routine surveillance colonoscopy was performed within 12 months of surgery. Patients were followed every 3 months for the first year, every 6 months for the second, and once a year thereafter for at least 5 years. A patient was considered free of cancer if the clinical assessment and physical examination including digital rectal examination and sigmoidoscopy was normal. Radiological investigations (chest radiography, abdominal ultrasonography, computed tomography or magnetic resonance imaging) were performed if there was clinical suspicion of recurrent disease.

Local recurrence was defined as disease detected within the pelvis whether or not distant sites of recurrence were present.

Technique of extrafascial excision of the rectum

After mobilization of the sigmoid and descending colon and identification of the left ureter, the superior rectal vessels were identified and separated from the hypogastric nerves. The vessels were then divided 3–4 cm above the pelvic brim (low ligation). The posterior dissection followed the posterior aspect of the superior rectal artery which leads directly on to the fascia propria surrounding the mesorectum. Using long scissors and anterior traction of the rectum, the mesorectum and its surrounding fascia propria was sharply dissected from the presacral fascia. In most patients the junction of the upper rectum with the horizontal rectum was found to be tethered by the rectosacral fascia[3] which was looked for carefully and, when present, divided sharply. The dissection was carried forward posterior to the fascia propria up to the anorectal junction. Attention was then turned to the anterior dissection in which the

---

Paper accepted 20 November 1997

peritoneum was divided just posterior to the seminal vesicles and the dissection carried down on and in front of Denonvilliers' fascia. At approximately 1 cm below the base of the prostate, Denonvilliers' fascia was divided transversely and the dissection carried distally directly in front of the fascia propria as far as the pelvic floor. Having completed the anterior and posterior extrafascial dissections, the fascia propria surrounding the lateral aspects of the rectal tube was identified and the tissues lateral to it were divided sharply paying special attention not to broach the endopelvic fascia enclosing the pelvic autonomic nerve plexus. No formal block dissection of the pelvic lymph nodes was undertaken.

If the tumour was in the upper third of the rectum, at least 5 cm of rectal wall and 5 cm of mesorectum below the tumour margin was removed. If the tumour was in the lower two-thirds of the rectum, most of the rectum together with all the mesorectum was removed. The rectal stump was washed out with 4 per cent povidone–iodine as a precaution against anastomotic recurrence. The same solution was used to irrigate the pelvis after the rectum had been removed. Reconstruction was preferably done by the double-stapling technique[4]. From 1994, if the division of the rectum was within 2–3 cm of the dentate line, a short (6–8-cm limb) colonic pouch was created[5].

Results

Between September 1980 and November 1996, 124 consecutive patients (68 men and 56 women) with a median age of 67 (range 24–92) years were operated on for their first rectal cancer (*Table 1*).

It was possible to resect the tumour in 122 patients (98 per cent); 91 had anterior resection, 19 abdominoperineal resection, ten Hartmann's procedure and two proctocolectomy. In 100 patients the operation was considered to be curative. The median distal clearance margin was 3 (range 0·8–10) cm. The distribution of Dukes stage in the total series is shown in *Table 1*.

Early mortality and morbidity

One patient died 13 days after operation from complications secondary to a bleeding disorder. Anastomotic leakage occurred in nine (10 per cent) of the 91 sphincter-saving operations, all but two occurring from anastomoses in the lower third of the rectum. Seven (8 per cent) had major leaks (one patient had a defunctioning ileostomy) which required laparotomy. There were also two (2 per cent) minor leaks (both patients were defunctioned) causing little systemic upset; both resolved with conservative treatment. There were no deaths as a consequence of anastomotic leak.

Survival

Overall (crude) survival for the curatively and palliatively resected patients is shown in *Fig. 1*. The 5-year cancer-free survival rate for the total series was 68 per cent. The cancer-free survival rate in the 100 patients in the curative group was 81 per cent. *Fig. 2* shows the cancer-free survival rate in these patients according to Dukes stage.

Local recurrence

Six patients (6 per cent) developed a local recurrence among 102 patients who were available for a minimum follow-up of 24 months. Three of the recurrences developed in the palliatively resected group of patients and were also associated with systemic recurrence. In the curative group 84 patients (21 with Dukes A, 35 with Dukes B and 28 with Dukes C disease) were available for a minimum follow-up of 24 (median 73, range 24–180) months. Three (4 per cent) of them developed local recurrence. In two patients the recurrence was at the anastomotic line and associated with a very short distal resection margin (less than 1 cm). The other patient had at operation what was thought to be tumour extending beyond the rectum into the pouch of Douglas. However, microscopy of the removed specimen, while indicating tumour extending for 0·9 cm into the perirectal fat, showed a clear CRM.

Adjuvant therapy

Eight of the 84 patients in the curative group had adjuvant therapy comprising preoperative radiotherapy in two with very bulky tumours, postoperative radiotherapy in five (three had extensive infiltration of the mesorectum, two had a perforated carcinoma) and chemoradiotherapy in one. None of these patients developed local recurrence. Three patients have died, 17, 42 and 53 months after operation; the other five are still alive a median of 42 (range 24–85) months after surgery.

Positive resection margins and outcome

Eight (7 per cent) of the 122 patients who underwent extrafascial excision had tumour present at the CRM. In seven patients it was judged at surgery that tumour had extended to the pelvic side walls; three of these patients had liver metastases as well. Six of the eight patients who had a positive CRM died from widespread metastases (three had clinically detectable local recurrence as well) median of 16·2 (range 12–20) months after operation. The other two patients remain clinically free of tumour 19 and 4 months after operation.

Discussion

Local recurrence of cancer in the pelvis occurs in one in five patients treated surgically for rectal cancer[6]. It is rarely cured and most often gives rise to distressing and debilitating symptoms which are difficult to treat. The results of the present study show that if extrafascial excision of the rectum is performed and subsequent histological examination of the removed specimen shows the cancer is contained within the fascia propria then local recurrence is exceptional. Of the 122 patients who underwent extrafascial excision there were six in whom the cancer recurred locally. In three the tumour had already spread beyond the confines of the fascia propria at the time of surgery. Of the other three patients in whom the operation was thought to be curative the tumour recurrence occurred in two at the anastomotic line. In both, the surgical margin was less than 1 cm, which is a clear breach of accepted surgical practice (2 cm is the accepted lower limit[7]). The cause of the local recurrence that occurred in the remaining patient is open to conjecture; presumably residual cancer remained in the pouch of Douglas even though the circumferential resection margin was said to be free of tumour.

Other surgeons have also reported local recurrence rates after curative surgery for rectal cancer of around 5 per cent and with overall cure rates of about 80 per cent[8,9]. They have usually attributed these results to the fact that they performed total mesorectal excision (TME)[10]. The importance of adequate excision of the mesorectum is highlighted by the pathological studies demonstrating microscopic tumour deposits beyond the distal extent of intramural spread in up to 25 per cent of cases[10–12]. Indeed, TME has been endorsed as the new standard for the surgical treatment of rectal cancer in Norway and Sweden[13]. Although it is not always clearly stated, most detailed descriptions of TME indicate that the dissection is conducted in the extrafascial plane and most surgeons applying TME principles are actually performing extrafascial excision. Heald, who pioneered the concept of removing the whole mesorectum as a technique for preventing local recurrence, stressed the importance of dissecting in the so-called 'Holy Plane', which is in fact the areolar tissue just outside the fascia propria[14].

The results of the present series also shed light on the difficulties raised by studies in which the presence of cancer at the CRM has been noted. Studies in which standard surgical techniques were applied have shown that the CRM is positive in 20–25 per cent of patients judged at surgery to have had macroscopically complete excision and that a 'positive CRM' is highly predictable of local recurrence[15–18]. The present study shows that a positive CRM after extrafascial excision is less common (7 per cent) and is almost invariably associated with systemic disease and poor prognosis. These findings are in accord with those of Cawthorn *et al.*[19], who demonstrated a similar association between a positive CRM and systemic recurrence (not local recurrence) after TME.

It is proposed that the operation in which the rectum is removed in the anatomical plane outside the fascia propria should be called by its proper name, extrafascial excision. Surgeons usually regard alimentary tract mesenteries as posterior rather than circumferential structures, and the term 'extrafascial excision' highlights the necessity of performing a circumferential dissection outside the fascia propria in order to keep the incidence of local recurrence at the lowest possible level. Understanding the concept that rectal cancer confined within the fascia propria of the rectum can be removed with a very low local recurrence rate also has important implications and challenges for radiologists and oncologists.

Novel approach to combined defaecation and micturition disorders with rectovaginovesicopexy

R. SILVIS, H. G. GOOSZEN, T. KAHRAMAN, A. G. GROENENDIJK*,

Correspondence to: Dr R. Silvis, Kennemer Gasthuis Haarlem, Velserstraat 19, 2023 EA Haarlem, The Netherlands

Background This study was conducted to investigate the results of rectovaginovesicopexy (RVVP) in patients with combined defaecation and micturition disorders. RVVP was developed from a standard procedure for different forms of defaecation disorders (the rectovaginopexy (RVP)). It is only a limited extension to the RVP and results in elevation of all three pelvic compartments.

Methods In a consecutive series of 25 patients the effects or RVVP were evaluated prospectively. Information about the clinical history and results was obtained by a standard questionnaire filled out before and 3 and 12 months after operation. Dynamic defaecography was performed before and 3 months after RVVP. Before operation urodynamic studies were conducted.

Results RVVP improved constipation (14 of 18 patients improved, $P = 0{\cdot}001$), faecal incontinence (11 of 16 patients improved, $P = 0{\cdot}005$) and dysfunctional voiding (ten of 16 patients improved, $P = 0{\cdot}07$) without induction of these disorders. Overall urinary incontinence improved in 11 of 22 patients ($P = 0{\cdot}18$), with deterioration of urinary incontinence in three and induction of urinary incontinence in two of the patients. Patients with isolated urinary stress incontinence fared better (eight of 13 patients improved) than those with mixed urinary incontinence.

Conclusion RVVP provides satisfactory improvement of combined defaecation and micturition disorders. The benefits of a limited extension of the RVP seem to outweigh potential side-effects such as deterioration or *de novo* defaecation or micturition disorders.

Disorders of anorectal function should not be considered in isolation but are part of a spectrum of pelvic floor dysfunction[1,2]. Many authors have drawn attention to the combined occurrence of anorectal, gynaecological and urological symptoms[3–9]. This coexistence of symptoms is not surprising in view of the close anatomical relation and common innervation of the pelvic floor structures and shared susceptibility to damage from childbirth, chronic straining at stool and hormonal changes associated with the menopause[1].

Previous experience in the treatment of patients with the combination of constipation and faecal incontinence by rectovaginopexy (RVP)[10] revealed concomitant relief of urinary incontinence in some patients and deterioration in others. The reason for this variable effect on urinary incontinence was unclear. In this study patients with different combinations of defaecation and micturition disorders and anatomical abnormalities (rectocele, internal rectal intussusception, enterocele, cystocele and/or vaginal vault or uterovaginal prolapse) were treated by rectovaginovesicopexy (RVVP) to elevate all three compartments of the female pelvis. RVVP should accomplish elevation of the vesicourethral junction and improve urinary incontinence as a result of abdominal pressure transmission to the vesicourethral junction. The main purpose of the study was to investigate the effect of addition of vesicopexy to RVP on disordered defaecation and coexisting micturition problems.

Patients and methods

Clinical assessment

From March 1993 to March 1994, a consecutive series of 25 patients with a mean(s.d.) age of 54(11) (range 38–70) years underwent RVVP. All operations were supervised or performed by one of the authors (L.W.M.J.). Information about the clinical history was obtained by a standard questionnaire before and 3 and 12 months after operation.

Constipation was divided into four categories to quantify the effect of the operation. In addition, constipation was scored according to the definition of Drossman *et al.*[11] to make comparisons with the literature[12–14]. Patients with grade 3 and 4 constipation were considered constipated according to the Drossman criteria.

Faecal continence was graded according to Browning and Parks[15] into four categories.

Dysfunctional voiding and urinary continence were divided into four categories as well. Based on the history as well as urodynamic physiology studies, patients were classified as having urge or stress urinary incontinence or both. The clinical history concerning urinary incontinence was compared with urodynamic findings. In all cases the indication for RVVP was determined by a surgeon, a urologist and a gynaecologist. All patients had had previous pelvic surgery (mean 1·7 operations). Constipation was the indication for surgery in ten patients and faecal incontinence in 15. Overall, 18 patients were constipated, ten of whom reported constipation as the primary symptom. The other eight had constipation in combination with faecal incontinence as the main symptom (*Table 1*). In 22 patients urinary incontinence was a secondary symptom. Symptoms leading to surgery were accompanied by abnormal findings at physical examination (*Table 2*) and anatomical abnormalities on dynamic defaecography (rectocele, internal rectal intussusception, enterocele or combined abnormalities).

Dynamic defaecography

Dynamic defaecography, as described by Mahieu *et al.*[16,17] was also performed before and 3 months after RVVP. Data were obtained by analysing videotapes and were reviewed by a panel unaware of patients' symptoms and whether defaecograms were made before or after RVVP. As well as rectal barium contrast and contrast coating of the vagina, in all cases, oral contrast was given to detect an enterocele. Depth of a rectocele was classified according to Shorvon *et al.*[18] and measured as the maximum depth of the anterior bulge beyond the expected and extrapolated line of the anterior rectal wall. Rectocele, intussusception and enterocele were divided into three grades (*Table 3*). Protrusion of an intussusception beyond the anal canal was called rectal prolapse. Patients with signs of a non-relaxing puborectalis syndrome were excluded based on both clinical symptoms and radiographic findings.

Urodynamic physiology studies

Urodynamic investigations were performed before RVVP by filling and diuresis cystometry with pressure flow studies[19]. Genuine stress incontinence (GSI), detrusor overactivity/measured urge incontinence (MUI), urethral instability, maximum flow rate, detrusor pressure during voiding, urethral resistance and maximum urethral closing pressure (UCP) were determined.

Surgical procedure

The RVVP evolved out of the rectovaginopexy (RVP)[10]. The technique, as described in detail below, aims at avoiding damage to the hypogastric plexus and pelvic autonomic nerves by dissection of the peritoneum only, without mobilization of the dorsolateral side of the rectum and with preservation of the lateral ligaments.

RVVP, rectovaginovesicopexy. §Wilcoxon paired signed rank test

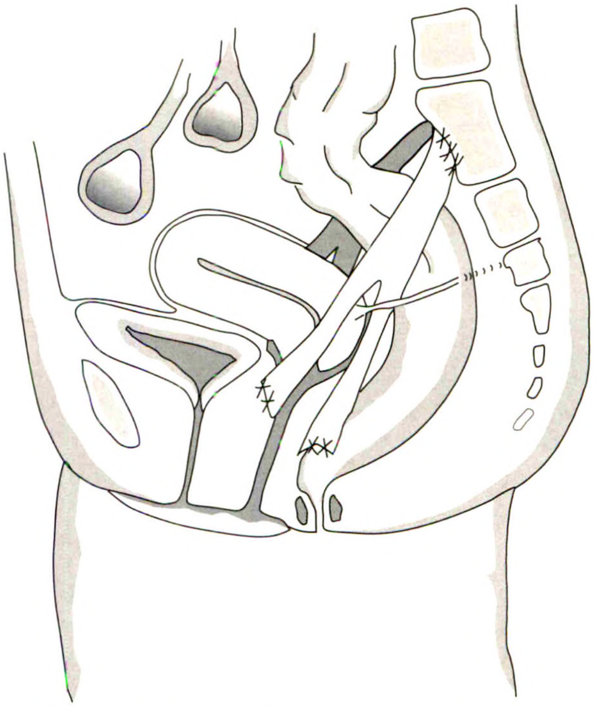

Fig. 1 Schematic representation of the polytetrafluoroethylene strip fixed to the promontory with fixation of the dorsal arms of the strip to the anterolateral side of the rectum. The ventral arms of the strip are fixed to the dorsal side of the elevated bladder

The operation is performed through a midline laparotomy. The peritoneum on both sides of the rectum and in the rectouterine pouch is incised and the peritoneum is dissected from the underlying structures in lateral and caudal directions. Thereby, no nerves are endangered and both ureters are left undisturbed. The space between the rectum and vagina is dissected, in the avascular plane, down to the level of the pelvic floor. Hereafter, the whole rectum is mobile and the part of the rectum originally situated at the bottom of the pouch of Douglas can be brought up to the promontory. The lateral ligaments are not divided.

Subsequently the space between the vagina and bladder is dissected. A small hole is made by blunt dissection between the rectum and the promontory. A polytetrafluoroethylene (PTFE) (GORE-TEX; W.L. Gore, Woking, UK) strip of 20 × 3 cm is fixed in the middle to the promontory with non-absorbable sutures. The free ends of the strip are divided, creating four arms. The PTFE strips are not placed through the broad ligament. The dorsal arms of the strip run posterior and the ventral arms anterior to the broad ligament. Uterine vessels are not divided. The two dorsal arms of the strip are sutured to the antero(lateral) side of the stretched rectum as low as possible (i.e. well below the pouch of Douglas). Closure of the space between the rectum and vagina, to prevent or treat a uterine or vaginal prolapse, is achieved by suturing the insertions of the uterosacral ligaments to the splitting point of the PTFE strips with non-absorbable sutures. The two other arms of the PTFE strips are fixed to the dorsal side of the elevated bladder. A suction drain is placed to prevent haematoma formation. The peritoneum is trimmed and reefed by a continuing running resorbable suture to cover the PTFE strip (*Fig. 1*).

Statistical analysis

Data not normally distributed were compared using Wilcoxon's paired signed rank test. $P < 0.05$ was considered statistically significant.

Results

Clinical data

The effect of RVVP on constipation in all 25 patients is shown in *Fig. 2*. Some 12 months after RVVP, constipation was completely abolished in nine of 19 patients. One patient developed grade 2 constipation. According to the definition of Drossman *et al.*[11], constipation was cured in 14 of 18 patients ($P = 0.001$) and no patient developed constipation.

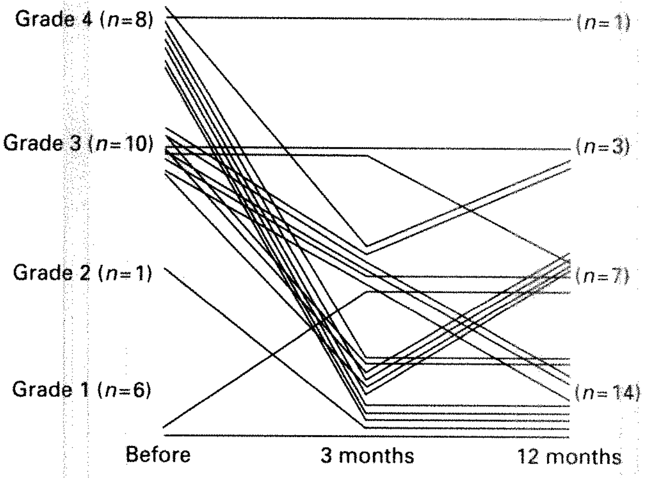

Fig. 2 Effect of rectovaginovesicopexy on constipation. Grade 1, not constipated; grade 2, constipated once in a while (less than 25 per cent of the time); grade 3, constipated frequently (25–75 per cent of the time); grade 4, always constipated (more than 75 per cent of the time). According to the definition of Drossman *et al.*[11], only patients with grades 3 and 4 are constipated

Fig. 3 illustrates the effect of RVVP on faecal incontinence. In 11 of 16 patients faecal continence improved ($P = 0.005$).

RVVP had a positive, although not significant, effect on dysfunctional urinary voiding 12 months after operation ($P = 0.07$). At 12 months the feeling of dysfunctional voiding was abolished completely in seven of 16 patients, diminished in three, unchanged in three and in three other dysfunctional voiding deteriorated (*Fig. 4*).

RVVP had a variable effect on urinary incontinence ($P = 0.18$ at 12 months). At 1 year after RVVP, six of 22 patients were completely continent of urine. Urinary incontinence improved in a further five patients, was unchanged in eight and deteriorated in three. Two patients developed some degree of urinary incontinence (*Fig. 5*). The patients with an isolated history of urinary stress incontinence (USI) fared better than those with

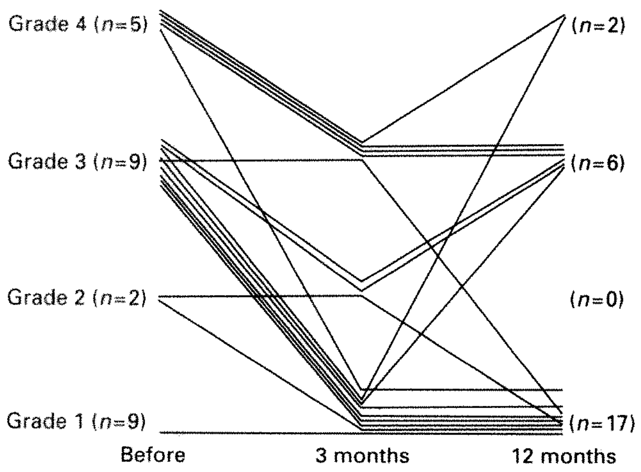

Fig. 3 Effect of rectovaginovesicopexy on faecal incontinence. Grade 1, completely continent; grade 2, continent to stools but incontinent to flatus; grade 3, incontinent to liquid stools and flatus but normally continent to solids; grade 4, completely incontinent

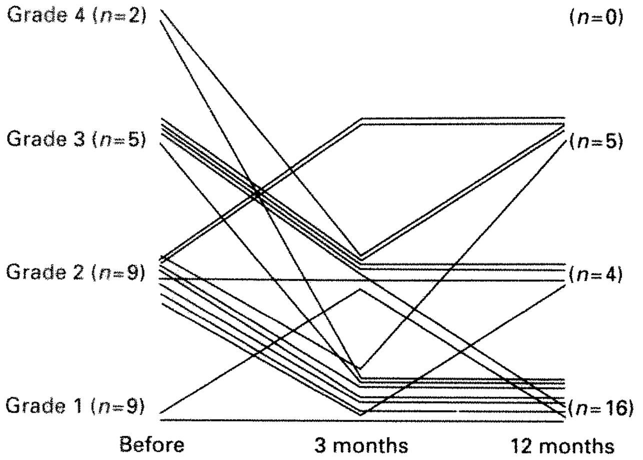

Fig. 4 Effect of rectovaginovesicopexy on dysfunctional voiding. Grade 1, normal feeling of bladder emptying with normal stream; grade 2, once in a while squeezing at micturition and a feeling of incomplete bladder emptying; grade 3, frequent squeezing at micturition with bladder emptying in several attempts; grade 4, always squeezing and always a feeling of incomplete bladder emptying, or self-catheterizing

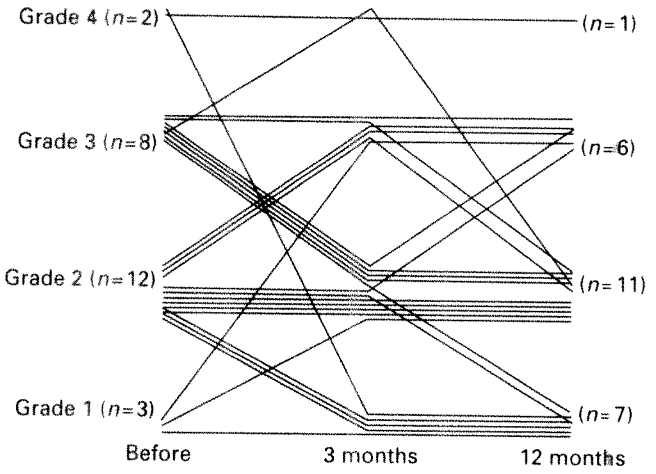

Fig. 5 Effect of rectovaginovesicopexy on urinary incontinence. Grade 1, no urinary incontinence; grade 2, loss of small amounts of urine; grade 3, regular loss of larger volumes (more than 5 pads five per day); grade 4, complete urinary incontinence

both USI and a history of urinary urge incontinence (UUI). In 13 patients with USI only, urinary incontinence improved in eight, whereas in a further eight patients with both USI and UUI only two improved. Urinary incontinence improved in one patient with UUI only. Of three patients without urinary incontinence, one remained completely continent to urine, one developed grade 2 USI and one grade 3 UUI.

Dynamic defaecography

Before operation a rectocele was found in 20 patients, intussusception in eight and enterocele in ten. After RVVP, these values decreased to ten, zero and one respectively (*Table 3*). Six of the remaining ten rectoceles were smaller than before RVVP and four did not change in size (all grade I rectoceles). Only one patient had a rectocele greater than 2 cm after RVVP. In four patients preoperative and/or postoperative defaecograms were lacking because they refused to undergo the procedure.

Urodynamic physiology studies

Preoperative urodynamic physiology studies were available for 21 patients. Clinical history was compared with urodynamic findings. In 13 patients urodynamic findings of the presence or absence of stress incontinence were concordant with the history. Eight patients had USI without GSI. In 16 patients urodynamic findings concerning the presence or absence of urge incontinence were concordant with the history. Four patients had a history of UUI without urge incontinence at urodynamic investigation (further described as MUI), and one had MUI without a history of UUI.

At urodynamic investigation seven patients had GSI; four showed improvement after RVVP, in two urinary incontinence did not alter and in one symptoms deteriorated. Four patients with MUI were identified; two improved and in the other two urinary incontinence deteriorated. In the two patients with GSI as well as MUI, urinary incontinence did not improve. In eight patients neither GSI nor MUI was determined, although seven of these patients had a history of urinary incontinence. Maximum UCP before operation did not have any predictive value in determining patients who ultimately had no relief of urinary incontinence.

Discussion

This pilot study investigated not only the effect of RVVP on defaecation disorders but focused specifically on the effect on frequently encountered accompanying micturition disorders. RVVP is only a limited extension of the RVP (the authors' standard procedure for different forms of defaecation disorders) with concomitant vesicopexy resulting in elevation of all three pelvic compartments. The question addressed was whether the benefits of this limited extension of RVP in terms of improvement of micturition disorders outweighed potential side-effects such as deterioration of already disordered defaecation or micturition and/or the induction of *de novo* micturition disorders. To the authors' knowledge no previous study has focused on such an integrated operative approach to defaecation and micturition disorders.

RVVP improved constipation in 14 of 18 patients. No patient developed constipation. This compares favourably with other types of abdominal rectopexy, especially when the lateral ligaments of the rectum are divided[12,20,21]. In 11 of 16 patients faecal incontinence improved and in eight of the 16 faecal incontinence was cured. No patient developed faecal incontinence. Improvement of faecal incontinence after rectopexy as reported in the literature ranges from 50 to 90 per cent; alterations in, or coexistence of, urinary incontinence is not mentioned[13,20,22–24].

Although dysfunctional voiding improved in ten of 16 patients and urinary incontinence in 11 of 22, three of the patients reported deterioration of urinary incontinence, whereas two developed incontinence. Patients with stress incontinence fared better (eight of 13 with USI and four of seven with GSI improved) than those with combined stress and urge incontinence (two of eight improved). The patient's history appears to be unreliable in determining GSI or detrusor overactivity[25]. In the present patients the diagnosis of both USI and UUI was made more often on the history than by urodynamic assessment showing GSI or detrusor overactivity. Urodynamic assessment is considered as the criterion standard in determining stress or urge incontinence although urodynamic assessment is a rather unphysiological reflection of a moment in an incontinent patient's life[25,26]. The fact that in seven patients neither GSI nor detrusor overactivity was demonstrated despite a clear history of loss of urine is an illustration of this problem.

Comparison of the effects of RVVP on dysfunctional voiding and urinary incontinence with surgical procedures for USI that address the bladder compartment only is hampered by differences in patient population. Studies on the effect of surgical treatment of urinary incontinence usually do not mention concomitant symptoms, such as dysfunctional voiding, faecal incontinence or constipation. The Marshall–Marchetti–Krantz procedure, Burch colposuspension and needle suspensions (Stamey–Pereyra) for GSI have a cure rate of 70–90 per cent. However, these procedures are accompanied by *de novo* incontinence as well. *De novo* voiding disorders and *de novo* detrusor instability are reported in 6–12 and 6–11 per cent of patients respectively[27]. RVVP did not induce voiding disorders, although in three of 16 patients the feeling of dysfunctional voiding was aggravated by one grade. *De* *novo* detrusor instabilities could not be determined because of lack of postoperative urodynamic physiology studies.

Dynamic defaecography made it clear that, 3 months after RVVP, the anatomy of the posterior and middle compartment of the pelvis was grossly restored (*Table 3*). Besides nine grade I rectoceles, which is within normal physiological range[18,28], only one grade II rectocele and one enterocele were noticed. None of the contrast-coated vaginas showed any sign of vaginal vault or uterovaginal prolapse or of a cystocele during dynamic defaecography.

In conclusion, RVVP provides improvement of constipation, faecal continence and dysfunctional voiding, without induction of these symptoms. A limited extension to the RVP improved patients' urinary incontinence in half of the cases, with an acceptable degree of deterioration of urinary incontinence. Prospective randomized studies comparing the effect of RVP with RVVP or of RVVP with RVP in combination with a Burch colposuspension are needed to elucidate further the role of an integrated approach to patients with combined urological and anorectal symptoms.

Proinflammatory mediator activity, endogenous antagonists and the systemic inflammatory response in intra-abdominal sepsis

C. H. WAKEFIELD, G. R. BARCLAY*, K. C. H. FEARON, A. S. GOLDIE, J. A. ROSS, I. S. GRANT†, G. RAMSAY, J. C. HOWIE and the Scottish Sepsis Intervention Group

Background Severe intra-abdominal sepsis continues to carry a high mortality rate. The physiological response to sepsis in this condition and its relationship with proinflammatory mediators and their endogenous antagonists require further clarification.

Methods Fifty-seven patients were stratified by Acute Physiology And Chronic Health Evaluation (APACHE) II score at the time of admission to an intensive care unit (group 1, score of less than 20; group 2, score of 20 or more). Serial measurements of clinical and immunological variables were made.

Results Non-survivors from group 2 had a raised acute physiology score ($P = 0{\cdot}01$), a higher peak serum interleukin (IL) 6 concentration ($P = 0{\cdot}03$) and a depressed level of endogenous immunoglobulin (Ig) G class antiendotoxin core antibody ($P = 0{\cdot}005$). In group 1, although organ failure score increased progressively in non-survivors, physiology score and peak IL-6 level were similar to those in survivors, and endogenous IgG class antiendotoxin core antibody titre rose ($P = 0{\cdot}02$). In both groups IL-1 and tumour necrosis factor α were detected infrequently, but their natural antagonists were present in much higher concentrations in both survivors and non-survivors. Levels of C-reactive protein were raised in both but were not significantly different between survivors and non-survivors.

Conclusion During the development of organ failure and death, the pattern of proinflammatory mediators and their endogenous antagonists can vary markedly and may in part be determined by the extent of the initial physiological disturbance.

Despite current supportive care, correct surgical practice and antimicrobial therapy, the mortality rate from severe intra-abdominal sepsis remains at 40–50 per cent[1–3]. At present it seems that the major threat to survival comes not from the underlying infection but from the progressive derangement of organ function as a consequence of the systemic inflammatory response and its sequelae[4]. The severity of the acute physiological derangement associated with sepsis acts as an independent risk factor for mortality in intra-abdominal infection[5,6].

The administration of endotoxin to humans can induce the clinical signs associated with the sepsis syndrome[7], these manifestations being related to increased production of endogenous cytokines, which in turn can reproduce aspects of sepsis syndrome[8,9]. The cytokine responses to endotoxin vary considerably between individuals[10,11], and may in turn influence the degree of the systemic inflammatory response. Although raised levels of circulating endotoxin and the proinflammatory cytokines interleukin (IL) 1β, tumour necrosis factor (TNF) α and IL-6 correlate to some degree with the severity and outcome of sepsis[12–15], the prognostic usefulness of circulating cytokine concentrations is often less than that of clinical variables[3]. In addition, blockade of proinflammatory mediators by passive immunization against endotoxin[16], TNF-α[17] and IL-1β[18] has failed to improve survival in patients with sepsis, despite the promise of animal studies[9,19,20]. Delay to treatment and the presence of naturally occurring antagonists, such as endogenous antiendotoxin antibodies, soluble TNF receptor and IL-1 receptor antagonist (IL-1ra), may partially explain such results[21–23].

The extent to which the interplay between proinflammatory mediators and endotoxin with their naturally occurring antagonists influences outcome is unknown and it is uncertain whether the interplay corresponds with the level of physiological disturbance. The authors have previously reported a large heterogeneous group of patients with sepsis syndrome who were admitted to intensive care units (ICUs)[24]. This paper examines further the subgroup of patients with intra-abdominal infection. Patients were stratified into two risk categories according to Acute Physiology And Chronic Health Evaluation (APACHE) II score[25], so that the importance of proinflammatory and anti-inflammatory events in relation to outcome could be assessed at the same time as recognizing confounding factors such as age, pre-existing medical conditions and disease severity. The present study examines the relationship between outcome and circulating levels of plasma endotoxin, IL-6 and C-reactive protein (CRP), IL-1β and mediator antagonists, the significance of acute physiology and organ failure scores, and 30-day mortality.

Patients and methods

Patients

A group of 57 patients in ICUs with sepsis syndrome of abdominal origin were studied over a 16-month period in five

Paper accepted 6 November 1997

units. Patients were enrolled if there was clinical or radiological suspicion of intra-abdominal infection (this being confirmed at laparotomy) and if they fulfilled all the criteria for sepsis syndrome: (1) hyperthermia (temperature greater than 38°C) or hypothermia (less than 35·5°C); (2) tachycardia (more than 90 beats per min in the absence of β-blockade); (3) tachypnoea (more than 20 breaths per min) or requiring mechanical ventilation; and (4) evidence of failure of one or more end-organs (defined as a plasma lactate concentration greater than 1·2 mmol l^{-1} or base deficit above 5 mmol l^{-1} or systemic vascular resistance lower than 800 dyn s/cm^5; ratio of arterial partial pressure of oxygen to fraction of inspired oxygen (P_{aO_2}/F_{iO_2}) lower than 30 kPa or P_{aO_2} less than 9·3 kPa; urine output less than 120 ml over 4 h; Glasgow Coma Score less than 15 in the absence of a neurological lesion[24,26]).

Approval for the study was granted by each centre's ethical committee and written informed consent was obtained from the patient or a relative. Patients were followed until death or for 30 days. Severity of illness was scored on enrolment using the APACHE II system[27]. Organ failure was assessed daily for 7 days and at day 10 using an organ failure score[28]. Terms employed for the description of intra-abdominal infection and types are those recommended and defined by the Joint Working Party of the Surgical Infection Society[25].

Patient stratification

Patients were stratified using the APACHE II score. Patients in group 1 ($n = 24$) had an APACHE II score of less than 20 and those in group 2 ($n = 33$) had a score of 20 or more at study entry. The predicted mortality rate of these two groups, weighted for abdominal infection, was less than 58 per cent for group 1 and more than 64 per cent for group 2[27].

Blood sampling protocol

Blood was drawn daily for 7 days and on day 10 by venepuncture or from an indwelling arterial line. Blood (20 ml) was collected for aerobic and anaerobic culture at two time points in the first 24 h. Blood for endotoxin and endogenous antiendotoxin core antibody (EndoCAb) measurements was drawn into heparinized endotoxin-free tubes, centrifuged and the resulting plasma stored at −20°C. Blood for cytokine and CRP measurements was drawn at study entry and on consecutive days for 1 week and again on day 10. Blood was allowed to clot in glass tubes at room temperature, centrifuged and the resulting serum was stored at −20°C[24].

Laboratory assays

IL-1ra was measured by enzyme-linked immunosorbent assay (ELISA) (R&D Systems, Minneapolis, Minnesota, USA) according to the manufacturer's instructions. Type I soluble TNF receptor (sTNFr55) was detected by sandwich ELISA (anti-sTNFr55 antibodies were kindly donated by Dr W Buurmann), as described previously[24]. Plasma endotoxin concentrations were determined with the Coatest Endotoxin (Chromogenic) test kit (Chromogenix; Quadratech, Epsom, UK). The assay was sensitive to levels of endotoxin over 0·05 units ml^{-1}. Immunoglobulin (Ig) G and IgM EndoCAb were measured with an ELISA as described previously[21,24]. Depletion of EndoCAb was defined as lower than the tenth centile of the value in a group of healthy adult blood donors. The tenth centile for IgG EndoCAb was 33·7 IgG median units (GMU) per ml, and for IgM EndoCAb it was 39·7 IgM median units per ml.

CRP was measured by a standard ELISA (DAKO; Ely, Cambridgeshire, UK), samples being diluted 1:30 000. The ELISA for IL-6 used a murine monoclonal antihuman IL-6 antibody (Boehringer-Mannheim, Mannheim, Germany) and a goat polyclonal antihuman IL-6 antibody (British Biotechnology, Abingdon, UK), followed by a peroxidase-conjugated antigoat IgG (Sigma, Poole, UK).

Statistical analysis

Results are given as the mean(s.e.m.). Group frequencies were compared with the χ^2 test. Continuous data were compared with the Mann–Whitney *U* test and Scheffé's method for multiple comparisons was used to determine the significance of differences at individual time points. To assess the influence of variables on overall survival, time-dependent covariates were entered into the Cox regression model. Differences were considered significant when the probability of their arising by random sampling error was less than 1 in 20 ($P < 0·05$).

Results

Patients

The 57 patients (31 men and 26 women) had a mean(s.e.m.) age of 65(2·1) years. On admission to the ICU the mean(s.e.m.) APACHE II score was 22(1) and the overall mortality rate was 58 per cent (33 of 57 patients). Non-survivors were not significantly older than survivors (68(3) *versus* 62(3) years; $P = 0·09$, Mann–Whitney *U* test), but their APACHE II scores were significantly higher (24(1) *versus* 20(1); $P = 0·025$, Mann–Whitney *U* test). Non-survivors were more likely to have been shocked before study entry (25 of 33 *versus* 11 of 24 patients, $P < 0·05$). At the time of admission, serum creatinine levels were higher in non-survivors (192·1(11·6) *versus* 146·9(25·1) μmol l^{-1}; $P = 0·02$, Mann–Whitney *U* test); serum albumin and bilirubin levels were similar in survivors and non-survivors, as was the prothrombin time and the incidence of malignancy (*Table 1*).

Operative findings

The stomach and duodenum were identified more frequently at laparotomy as the source of intra-abdominal infection in non-survivors (15 of 33 *versus* four of 24 in survivors, $P < 0·05$). The remaining anatomical origins of sepsis occurred with similar frequency. All patients underwent an operative procedure for intra-abdominal infection. No clear differences emerged with regard to the bacteriology of primary cultures from the peritoneal

Table 1 Patient characteristics

	Total ($n = 57$)	Survivors ($n = 24$)	Non-survivors ($n = 33$)	*P*

*Values are mean(s.e.m.). APACHE, Acute Physiology And Chronic Health Evaluation. †Mann–Whitney *U* test; ‡χ^2 test cavity, and the nature of the contaminant did not influence outcome. Positive blood cultures were obtained in eight patients (14 per cent) during this time, but this was not associated with an unfavourable outcome. At the time of study entry, 91 per cent of patients were receiving antibiotic therapy. In three cases the cover provided was considered to be inappropriate for the organisms typically encountered in intra-abdominal infection (one non-survivor from group 1 and two survivors from group 2). Ten alterations in antibiotic treatment were made based on microbiological findings; in six patients these alterations were considered to be inadequate (two non-survivors and two survivors from group 1, one non-survivor and one survivor from group 2). Eleven of the 33 patients who died did so as a result of progressive organ failure without apparent clinical or radiological evidence of ongoing intra-abdominal infection. At the time of death 15 patients had evidence of persistent abdominal infection (group 1, four; group 2, 11) and seven had concurrent nosocomial infections (group 1, two; group 2, five).

Acute physiology or organ failure scores and the acute phase response

The mean(s.e.m.) acute physiology score (APS) of non-survivors was greater than that of survivors at study entry (19(1·0) *versus* 15(1·0); $P = 0{\cdot}004$, Mann–Whitney *U* test) and throughout most of the study period (*Fig. 1a*). Similarly the Goris organ failure score (GOFS) was greater in non-survivors at study entry (5(0·4) *versus* 4(0·4); $P = 0{\cdot}015$, Mann–Whitney *U* test) and throughout the study period (*Fig. 1b*). When patients were stratified according to admission APACHE II score, ten of the 24 patients in group 1 had died at 30 days compared with 23 of 33 in group 2 ($\chi^2 = 5{\cdot}7$, 1 d.f., $P < 0{\cdot}025$; *Table 2*). In group 2 the APS of non-survivors was significantly higher than that of survivors in the early part of the study (*Fig. 2a* and *b*). Organ failure scores for the two groups revealed that non-survivors generally had a higher daily score during the study, the differences becoming statistically significant at day 3 in group 1 ($P < 0{\cdot}05$) and at day 2 in group 2 ($P < 0{\cdot}01$) (*Fig. 3a* and *b*).

Interleukin 6 and C-reactive protein

Mean(s.e.m.) serum IL-6 concentration at study entry was significantly higher in non-survivors (29 749(15 126) *versus* 6137(2185) pg ml^{-1}, $P = 0{\cdot}045$), as was peak IL-6 level (41 235(20 877) *versus* 6481(2155) pg ml^{-1}, $P = 0{\cdot}022$). In group 2, mean(s.e.m.) peak IL-6 concentration was significantly higher in non-survivors (55 193(28 999) *versus* 4620(2462) pg ml^{-1}, $P = 0{\cdot}03$). However, in group 1 peak IL-6 levels were not significantly different (9130(2516) *versus* 7810(3113) pg ml^{-1}, $P = 0{\cdot}22$) and the pattern of serum IL-6 concentration showed no early peak and no demonstrable differences at any time point (*Fig. 4a* and *b*). When both groups were considered together a peak IL-6 concentration greater than 4000 pg ml^{-1} was associated with an increased mortality rate (25 of 33 *versus* nine of 24; $\chi^2 = 6{\cdot}39$, 1 d.f., $P < 0{\cdot}025$). CRP profiles were similar in both group 1 and group 2, for both survivors and non-survivors (*Fig. 5a* and *b*).

Endotoxin and endogenous antiendotoxin core antibodies

At enrolment 40 patients (70 per cent) had detectable plasma endotoxin (15·8(5·9) units ml^{-1}) and during the study period 51 patients (89 per cent) had endotoxin detectable at one or more time points. Initial and peak endotoxin levels were not predictive of outcome and showed no correlation with the severity of illness as determined by either the simultaneous APACHE II score, APS or maximum daily GOFS. In group 1, IgG EndoCAb

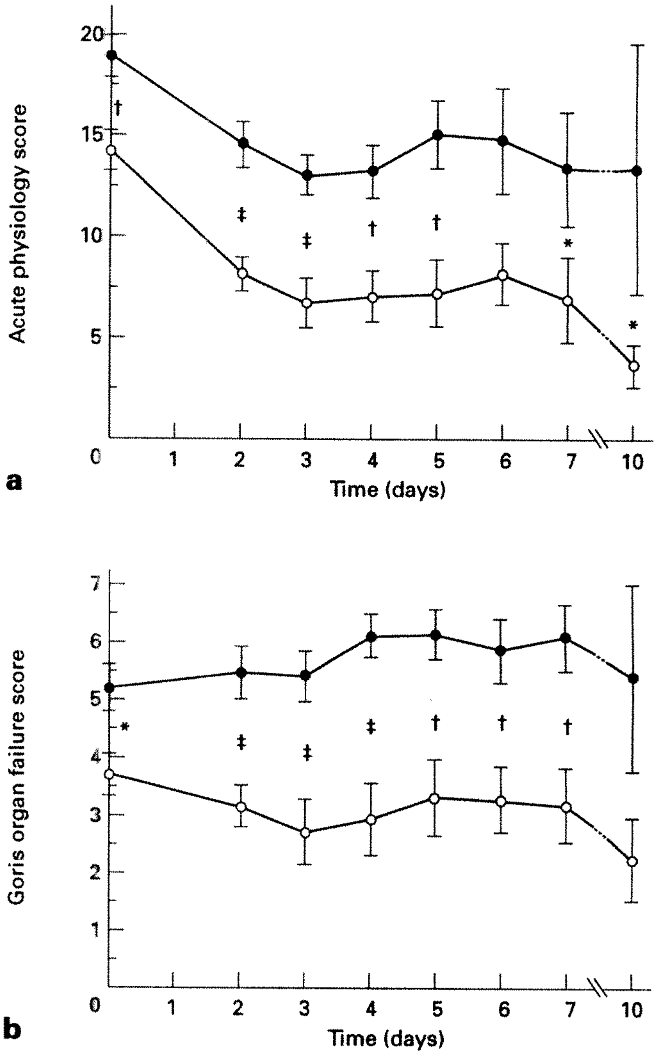

Fig. 1 Mean(s.e.m.) a acute physiology score and b Goris organ failure score for non-survivors (●) and survivors (○) over the 10-day study period. *$P < 0{\cdot}05$, †$P < 0{\cdot}01$, ‡$P < 0{\cdot}001$ (Mann–Whitney *U* test). All points indicated are also significant at the 95 per cent level for Scheffé's method for multiple comparisons

Table 2 Survival

	Day 0	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Day 10
Group 1 (*n* = 24)								
Survivors	14	14	14	14	14	14	14	14
Non-survivors	10	8	7	6	6	5	5	3
Group 2 (*n* = 33)								
Survivors	10	10	10	10	10	10	10	10
Non-survivors	23	15	11	11	10	9	5	4

concentration was similar in non-survivors and survivors at study entry, and tended to increase during the study period. On a day-to-day basis, this difference became significant at day 10 (*Fig. 6a*). In contrast, in group 2 overall IgG EndoCAb levels were lower in non-survivors, and on a day-to-day basis these differences were statistically significant at study entry (100·0(23·6) *versus* (216·9(50·4) GMU per ml; $P=0\cdot005$, Mann–Whitney U test) and in the latter part of the study period (*Fig. 6b*). IgG EndoCAb depletion (below the tenth centile of the value in a normal population) was observed in 12 patients (21 per cent) on entry, 11 of whom died; thus entry IgG EndoCAb depletion was associated with an increased mortality rate ($\chi^2=5\cdot47$, 1 d.f., $P<0\cdot025$). IgG EndoCAb depletion had no relationship with peak endotoxin levels (25·9(15·7) *versus* 26·5(15·3) units ml^{-1}; $P=0\cdot98$, for depleted and non-depleted). IgM EndoCAb showed a similar pattern of change (results not shown). Total IgG concentration measured at study entry was similar for non-survivors and survivors in group 1 (4·6(0·72) *versus* 4·27(0·62) units ml^{-1}, $P=0\cdot73$) and in group 2 (4·55(0·41) *versus* 4·87(0·81) units ml^{-1}, $P=0\cdot31$). There was, however, a positive correlation between IgG EndoCAb and total IgG levels measured at study entry ($r=0\cdot51$, $P<0\cdot001$, Pearson correlation).

Type 1 soluble tumour necrosis factor receptor and interleukin 1 receptor antagonist

sTNFr55 levels were higher at all three time points in non-survivors. Levels of sTNFr55 were not significantly higher in patients with detectable TNF-α compared with those in whom TNF-α was not detected (12·3(1·8) *versus* 12·5(0·9) ng ml^{-1}). Levels of sTNFr55 correlated with plasma creatinine ($r=0\cdot31$, $P=0\cdot029$). IL-1ra was present in concentrations some 2000-fold greater than those of IL-1β. IL-1ra detection was not associated with illness severity or shock at the time of study entry and was not predictive of death.

In patients with detectable IL-1β, IL-1ra was more abundant (98·6(23·8) *versus* 52·8(8·7) ng ml^{-1}, $P<0\cdot05$). IL-1ra levels were similar in non-survivors and survivors in groups 1 and 2 (46·0(13·2) *versus* 64·1(24·7) ng ml^{-1}, $P=0\cdot71$; 63·4(15·8) *versus* 47·8(14·8) ng ml^{-1}, $P=0\cdot6$).

Regression model and predictors of survival

The contribution to outcome of each variable analysed was evaluated by determining the coefficients for each in the Cox regression model. The results summarized in

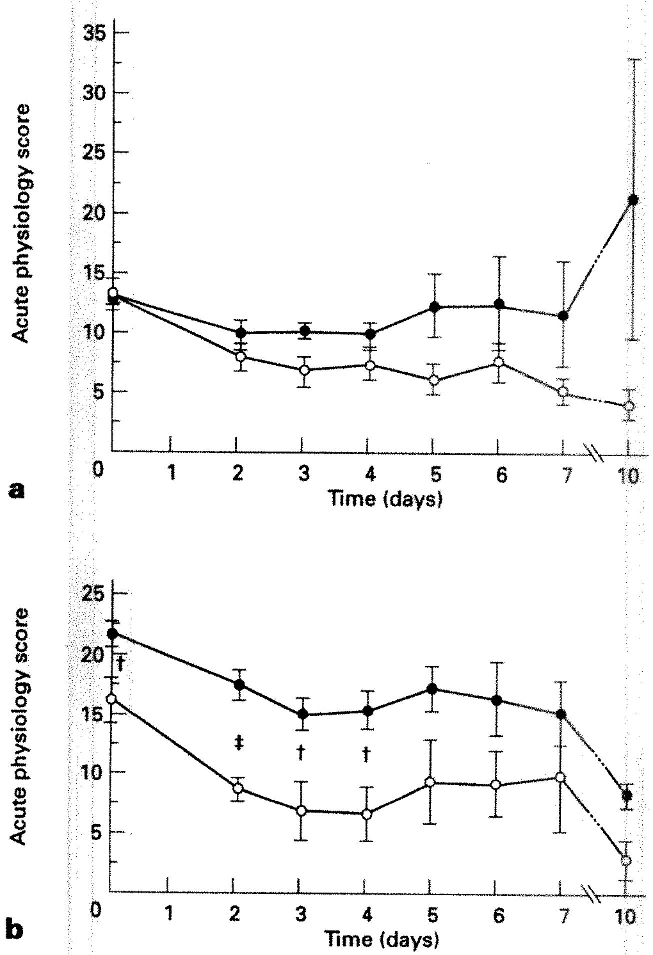

Fig. 2 Mean(s.e.m.) acute physiology score in **a** group 1 and **b** group 2 for non-survivors (●) and survivors (○) over the 10-day study period. †$P<0\cdot01$, ‡$P<0\cdot001$ (Mann–Whitney U test). All points indicated are also significant at the 95 per cent level for Scheffé's method for multiple comparisons

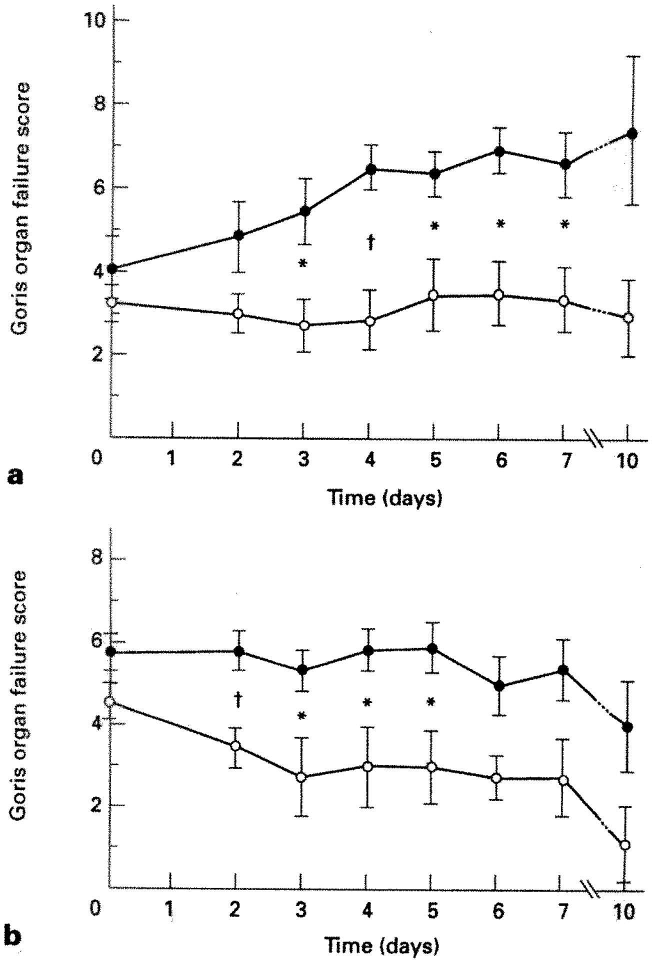

Fig. 3 Mean(s.e.m.) Goris organ failure score in **a** group 1 and **b** group 2 for non-survivors (●) and survivors (○) over the 10-day study period. *$P<0\cdot05$, †$P<0\cdot01$ (Mann–Whitney U test). Table 3 show that APS, GOFS and sTNFr55 level at study entry had a significant influence on outcome.

Discussion

Although the APACHE system is not specific for surgical infection, it has been advocated as the best means for risk stratification of patients with intra-abdominal infection[25]. In the present study in those with a low APACHE score (group 1), APS at study entry was identical for survivors and non-survivors, with little change over the study period. In the high APACHE score group (group 2), the initial APS of non-survivors was greater than that of survivors. A proportion of survivors was assigned to group 2 because of high scoring in the age and chronic health evaluation points. In contrast, non-survivors were entered into this group largely because of high APS. Such high APSs suggest either an overwhelming physiological insult, an exaggerated host response or a combination of the two as the main mechanism accounting for death in this group.

Clearly the trends in APS and GOFS in the present study are open to bias arising from changes in the underlying population as patients die. Indeed, in group 2 patients died more rapidly than those in group 1, and this inevitably influenced the patterns of APS and GOFS derived principally from patients who remained alive. Despite such changes in the population, both APS and GOFS act as independent predictors of outcome. Whilst it is accepted that APS is a product of the degree of physiological derangement and the level of medical intervention, it is likely to be the net physiological upset and loss of homoeostasis that is of importance.

Induction of the systemic inflammatory response by bacteria and their products has been well characterized[29–32] and the present study confirms the findings of others that endotoxin levels *per se* do not correlate with outcome. Endotoxaemia is a sporadic phenomenon[32] and measurement of endogenous antiendotoxin antibodies may be a more reliable indicator of endotoxin exposure[21]. In this series, patients with IgG EndoCAb depletion had a higher mortality rate. This depletion may reflect antibody consumption (as a result of binding to endotoxin) or in the longer term may reflect a primary failure in immunoglobulin production. In the present study on the first day of admission to the ICU, total IgG concentration was within the normal range for patients in both groups 1 and 2. This suggests that at least the initial reductions in EndoCAb levels were more related to antibody consumption than the result of non-specific mechanisms such as plasma dilution following resuscitation or a general failure of the immune system. Non-survivors in group 2 showed sustained depletion below that of survivors from either stratification group. In contrast, IgG EndoCAb levels increased progressively during the study in non-survivors from group 1. Such increasing EndoCAb levels probably reflect intermittent yet ongoing endotoxaemia, in

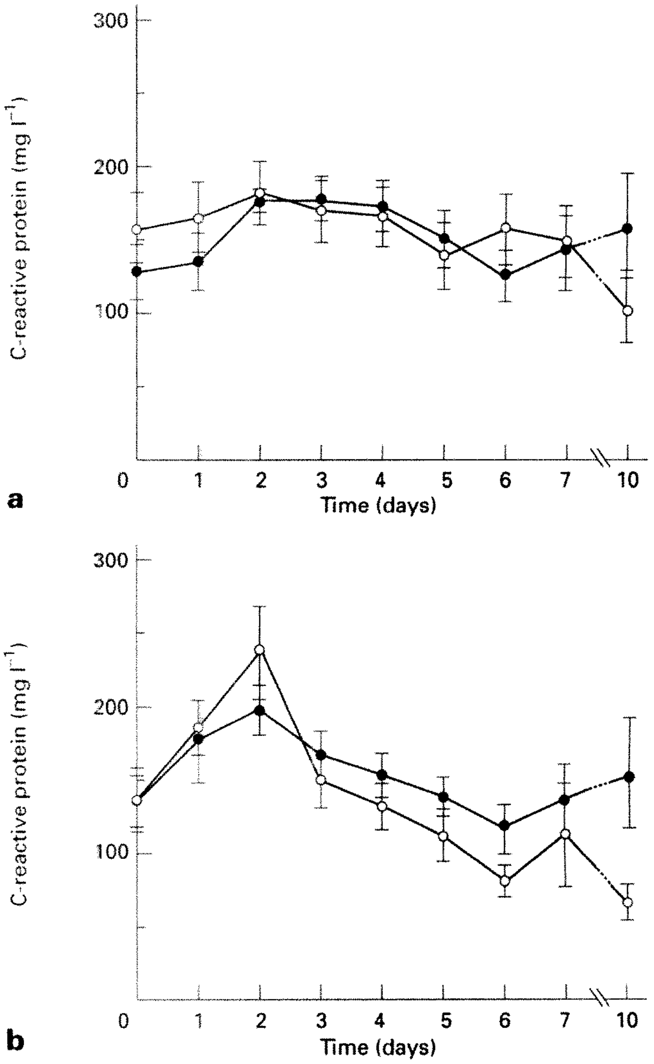

Fig. 5 Mean(s.e.m.) plasma C-reactive protein profiles in **a** group 1 and **b** group 2 for non-survivors (●) and survivors (○) over the 10-day study period

keeping with progressively rising APS and GOFS. However, unlike the patients in group 2, the initial systemic upset in group 1 is such that a normal antibody response is attainable upon initial and subsequent challenges by endotoxin. Alternatively, it is conceivable that the apparent rise in antibody titre is in part due to the death of patients who had become antibody depleted.

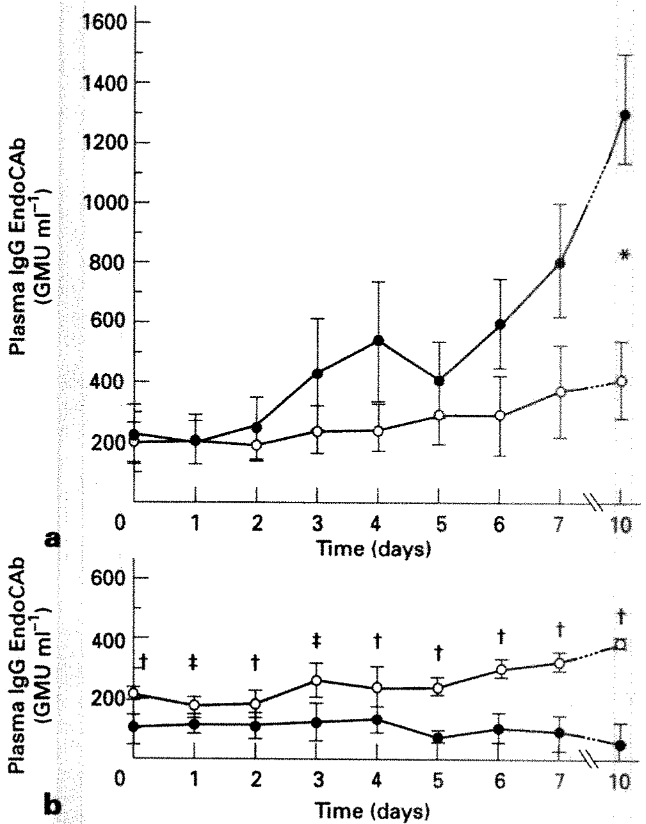

Fig. 6 Mean(s.e.m.) immunoglobulin G endogenous antiendotoxin core antibodies (IgG EndoCAb) in **a** group 1 and **b** group 2 for non-survivors (●) and survivors (○) over the 10-day study period. $^*P<0{\cdot}05$, $^\dagger P<0{\cdot}01$, $^\ddagger P<0{\cdot}001$ (Mann–Whitney *U* test). All points indicated are also significant at the 95 per cent level for Scheffé's method for multiple comparisons

It has been suggested previously that the severity of inflammation may be a key determinant of outcome in severe sepsis. In support of this, IL-6 levels have been related to the severity of tissue injury in elective surgery[33,34], and in the present study IL-6 levels were greatest in patients with the highest APS and organ failure scores. However, one of the many end-organ effects of IL-6 is the induction of hepatic acute-phase proteins such as CRP[35]. Despite the observed relationship between IL-6 levels and outcome, no detectable difference in serum CRP concentration was detected between survivors and non-survivors in either group. One explanation might be that the hepatic sites for IL-6 were saturated and circulating IL-6 levels exceeded local hepatic requirements for maximal induction of the acute-phase response. If CRP levels are taken as an index of the intensity of the inflammatory response, then the CRP profiles in the present study do not support the concept that it is the final level or duration of the inflammatory response *per se* that leads to death, as CRP levels were no different between survivors and non-survivors in either group 1 or group 2.

Non-survivors had significantly higher levels of type 1 soluble TNF receptor (sTNFr), a finding similar to that of Rogy *et al.*[36], who demonstrated that the sTNFr (representing the extracellular domain of the TNF receptor) is released in endotoxaemia. TNF exposure induces the release of sTNFr; thus the raised levels of sTNFr55 observed in non-survivors may reflect greater TNF activity or greater endotoxaemia. Furthermore, a sustained increase in the level of this antagonist is seen universally in critically ill patients, whereas in experimental endotoxaemia its presence is transitory[37]. This, of course, may not be necessarily be a reflection of a persistent systemic inflammatory response, but a failure of renal excretion of sTNFr. As in other studies[38], sTNFr55 level correlated with plasma creatinine concentration and may to some extent reflect renal impairment. The precise physiological importance of circulating cytokine antagonists such as sTNFr and IL-1ra (levels almost 2000-fold higher than those of IL-1β in the present study) remains to be elucidated. However, the failure of exogenous antagonists to improve outcome in sepsis syndrome suggests that the levels observed here may represent already replete endogenous pools.

The patients described in the present study are typical of patients in an ICU with severe sepsis from intra-abdominal infection. When stratified into risk groups by

APACHE II score, the majority of deaths occurred in patients with an initial score of 20 or more. For the patient group overall, and specifically for those in group 2, the APS was significantly higher both at study entry and throughout the ensuing 10 days in patients who died compared with that in those who survived. It is therefore apparent that a marked systemic response to infection is associated with a poor outcome. In patients in whom the initial physiological derangement is great, there is associated increase in the levels of IL-6, depletion of antiendotoxin antibodies and raised levels of soluble TNF receptors. There remain, however, non-survivors in whom the initial physiological upset is less and in whom the pattern of response appears to be different. IL-6 profiles follow those of their surviving counterparts; antiendotoxin antibodies are replete and rise as in a normal immune response. The mechanism of death in these patients is less clear and is worthy of further study.

If the initial systemic inflammatory response and ensuing organ dysfunction are a main influence on outcome, their development may be conditioned at several levels: first, at the level of induction of proinflammatory mediators by bacteria and their products; second, at the level of transcription of these mediators; and third, at the level of the effector cell and end-organ. Correct surgical practice should limit the bacterial inoculum, minimizing the induction process. With regard to host mediator responses (which may be predetermined genetically[39]), it is apparent that mediator and antagonist activity can differ markedly and their measurement in isolation cannot predict prognosis. The window of opportunity in modulating proinflammatory events is small and the exact requirements are difficult to define. However, early identification of idiosyncrasies in patient responsiveness and damage limitation at end-organ sites are avenues that should be explored further.

Background The extent of adhesion formation following both open and laparoscopic surgery remains unclear. This study aimed to evaluate the extent of postoperative adhesion formation after laparoscopic and open fundoplication in a rat model.

Methods Fifty-two male Sprague–Dawley rats were randomized into four groups: laparoscopic fundoplication ($n = 20$), open fundoplication ($n = 20$), laparoscopy ($n = 6$) and laparotomy ($n = 6$). Blood as well as intraperitoneal fluid was sampled for tumour necrosis factor (TNF) α measurement by enzyme-linked immunosorbent assay. All the rats were killed 3 weeks after operation, and adhesion formation was evaluated using a standardized scoring system.

Results There were no intergroup differences in body-weight gain after surgery. The overall mortality rate was 19 per cent and death was observed only in the fundoplication groups. Animals that had open fundoplication developed significantly more adhesions than those that underwent laparoscopic fundoplication (34 *versus* 21). Laparoscopic surgery induced predominantly parietal adhesions, whereas open surgery was more associated with visceral adhesions. The adhesions observed in the laparoscopic groups were significant thinner than those after open surgery and the tenacity of adhesions was decreased in laparoscopic compared with open surgery. The peak plasma level of TNF-α was reached during laparoscopic fundoplication, whereas the peak level was observed 3 h after open fundoplication. Intraperitoneal TNF-α levels showed no significant differences at 3 h.

Conclusion These findings indicate that laparoscopic fundoplication in rats leads to less severe adhesions of a different type (parietal) compared with those seen in the open controls.

The increasing use of minimally invasive surgery has played an important role in the development of abdominal surgery at the end of the 20th century. Along with the wider application of minimally invasive surgical procedures[1-3], there is a growing interest in the physiological changes that occur compared with those during open surgery[4-9]. Open surgical procedures may cause postoperative adhesion formation, leading to delayed postoperative complications such as abdominal pain[10,11], infertility[12,13] and bowel obstruction[14-16]. There are few fundamental scientific data available in the literature concerning the pathophysiological changes (local and systemic) that occur during laparoscopic surgery[17].

The development of laparoscopic surgery was based on experimental animal research. The use of large animals, such as pigs or dogs, in surgical research is also associated with increased costs[4,18]. The rat model has been shown to be an excellent training model for performing microsurgical procedures[4,19], providing the opportunity to investigate physiological changes, adhesion formation and immune function during different laparoscopic procedures. Several studies suggested that tumour necrosis factor (TNF) α, an acute-phase cytokine, may be one of the markers of peritoneal adhesion formation[17,20-22]. The purpose of this study was to develop a standardized laparoscopic procedure (i.e. Nissen fundoplication) in the Sprague–Dawley rat model and to compare it with an open approach to investigate and correlate adhesion formation and TNF-α production during and after surgery.

Materials and methods

Animals and study design

The experiments were approved by the Animal Ethics Committee of the State of Berne and performed according to international guidelines. Fifty-two male Sprague–Dawley rats, weighing 300–460 g (Süddeutsche Versuchstierfarm, Tuttlingen, Germany), were used for all the experiments. They were kept under normal laboratory conditions and were fed a standard rat chow (Kliba Futter, Basel, Switzerland) with tap water *ad libitum* before and after surgery. The rats were divided into four main groups. Groups 1 ($n = 20$) and 2 ($n = 20$) underwent laparoscopic or open fundoplication respectively and determination of TNF-α levels in plasma and peritoneal fluid following surgery. Group 3 ($n = 6$) underwent diagnostic laparotomy and group 4 ($n = 6$) diagnostic laparoscopy.

Blood and peritoneal fluid sampling for tumour necrosis factor analysis

Venous blood was sampled from the external jugular vein of all the animals on induction of anaesthesia, during the operation and 1, 3 and 24 h after operation, and collected into 5·5-ml Monovette AH (Nümbrecht, Sarstedt, Germany) tubes containing ammonium-heparin (15 units heparin per ml blood). Plasma was obtained by centrifugation for 10 min at 2500g and 4°C, collected into 1·5-ml plastic snap-cap tubes and stored at −20°C until analysis. Peritoneal fluid was obtained 3 h after surgery by vacuum absorption from the peritoneal cavity through a polythene tube (catheter) 0·58 mm in diameter and 4–5 cm

Paper accepted 6 November 1997

long, which was inserted at the end of the open and laparoscopic procedure and stored at −20°C until analysis. The Cytoscreen Rat TNF-α kit (Cannon, Labor Service GMBH, Wiessbaden, Germany) was used for the TNF-α analysis.

Surgical procedures

All the animals used in the study were anaesthetized by intraperitoneal injection of a mixture (1 ml per kg body-weight) of 25 ml 5 per cent glucose, 5 ml azepromazin, 5 ml xylazin and 10 ml ketamin. The animals were shaved and secured in a supine position to the small-animal operating table[4]. The instruments used for all the laparoscopic procedures were a 2·7-mm arthroscope with a 3-mm trocar sleeve, two 3-mm trocars (working channels) and 2·7-mm instruments (scissors, straight and angled forceps, needle holder; Wolf, Tuttlingen, Germany). Ordinary small-sized hand surgery instruments were used for all open procedures. All procedures were performed without using swabs or wearing gloves. In the open procedure the abdominal wall was retracted with two sutures, so iatrogenic manipulation at this side was minimal.

Laparoscopy was performed through a 3-mm abdominal wall incision, midway as described by Berguer *et al.*[4]. Pneumoperitoneum was established with carbon dioxide insufflation up to 4 mmHg (abdominal pressure). Diagnostic laparoscopy (no procedure performed) lasted 30 min, after which all the trocar sleeves were removed and the wound closed with two single stitches. Laparoscopic fundoplication started with blunt dissection of the adhesions between the caudate liver lobe and the lesser curvature. The oesophagus, left gastric artery and anterior vagus nerve were identified and the oesophagus grasped and retracted anteriorly. Following this, an opening behind the oesophagus was created bluntly. The fundus of the stomach was grasped through the opening, pulled behind the oesophagus, turned ventrally and sutured extracorporeally with two 5/0 Vicryl sutures (Ethicon, Spreitenbach, Switzerland). A polythene tube 0·58 mm in diameter and 4–5 cm long was inserted through the left sleeve to the abdominal cavity for peritoneal fluid collection. The pneumoperitoneum was desufflated through the camera port and all the trocars were removed in order to prevent initial tissue attachments to the port sites.

All open procedures were performed using the same technique via a standardized 3-cm midline incision. Diagnostic laparotomy also lasted 30 min. Open fundoplication was performed with two 5/0 Vicryl single stitches. Before closure, a polythene catheter was inserted into the abdominal cavity for peritoneal fluid collection. The laparotomy was closed with a 3/0 Vicryl running suture in two layers.

Postoperative observation and determination of adhesion formation

The animals were observed in single cages for 24 h after operation until all the necessary blood and peritoneal fluid samples had been taken. After that, they were kept and observed under standard laboratory conditions. Three weeks after operation the animals were killed by decapitation and the abdominal cavity was opened by a wide inverted U-shaped laparotomy to investigate the extent and type of adhesion formation by two independent surgeons. The special criteria of Egea Moreno *et al.*[23], as shown in *Table 1*, were used to determine the extent of adhesions, as well as their localization, thickness, tenacity and vascularization.

Statistical analysis

Means were compared with an unpaired *t* test. $P < 0{\cdot}05$ was considered to be statistically significant.

Results

Operating time, body-weight, follow-up and death

The operating time ranged from 15 to 45 (mean 28) min for laparoscopic fundoplication and from 15 to 37 (mean 25) min for open fundoplication. All animals had a normal, proportional body-weight gain at 1, 2 and 3 weeks following surgery and there were no significant differences (data not shown). The overall mortality rate was 19 per cent and deaths occurred only in the two fundoplication groups (five deaths in each). Early death (from anaesthesia, bleeding, pneumoperitoneum) occurred in six animals and delayed death (due to septic complications) in four.

Table 1 Quantification of adhesion formation

Criterion	Comment
No. of adhesions	1 for each
Site of adhesions	
Pelvic fat body–abdominal wall	Parietal
Omentum–abdominal wall	Parietal
Intestine–abdominal wall	Parietal
Omentum–liver/stomach	Visceral
Intestine–intestine	Visceral
Liver–stomach	Visceral
Thickness of adhesions	
< 3 mm	
3–5 mm	
> 5 mm	
Tenacity	
Type I	Simple, without dissection
Type II	Dissection needed to separate adherent area
Type III	Dissection needed to cut the adhesion
Vascularization of adhesions	
Vascularized	
Avascularized	

Total adhesion score is the sum of each criterion (site of adhesions, thickness, tenacity and vascularization)

Adhesion formation

Number of adhesions. Five animals that underwent laparoscopic fundoplication, two that had diagnostic laparoscopy and two that had diagnostic laparotomy still had not developed adhesions 3 weeks after surgery, whereas adhesions were detected in all animals that had open fundoplication (*Table 2*). The 15 animals that had

Table 2 Adhesion formation after laparoscopic or open Nissen fundoplication

	Laparoscopic fundoplication ($n = 15$)	Open fundoplication ($n = 15$)
Animals with adhesions	10	15
No. of adhesions	21	34
Site of adhesions		
Parietal adhesions	13	5
Visceral adhesions	8	29
Intestine involved (bowel, stomach, liver)	11	30
Thickness of adhesions		
< 3 mm	12	3
> 3 mm	9	31
Tenacity		
Type I + II	12	6
Type III	9	28

There were no differences in vascularization between the groups laparoscopic fundoplication developed 21 adhesions, whereas 34 adhesions were detected in the 15 animals that underwent open fundoplication. Rats that had diagnostic laparoscopy and laparotomy ($n = 6$ each) developed five and six adhesions respectively. The number of adhesions differed significantly ($P < 0{\cdot}05$) between laparoscopic and open fundoplication groups. No significant differences were observed in comparison with the other groups.

Site of adhesions. Animals that had laparoscopic surgery (laparoscopic fundoplication and diagnostic laparoscopy) developed predominantly parietal adhesions (13 of 21 after laparoscopic fundoplication and all five after diagnostic laparoscopy), mostly between the small intestine (three) or omentum (ten) and the scars of the optical or working trocars of the abdominal wall. There was no predominance of adhesion formation between the optic and working trocars. Animals that only underwent laparotomy also developed more parietal adhesions (five of six) between the small bowel or the omentum and the laparotomy scar. Conversely, animals that underwent open fundoplication developed predominantly visceral-type adhesions (29 of 34), especially between the intestine (two), liver/stomach and omentum (six) as well as between the stomach and liver (21). The distribution of adhesions after open fundoplication was significantly different from that after laparoscopic fundoplication ($P < 0{\cdot}01$) and diagnostic laparoscopy and laparotomy ($P < 0{\cdot}01$). No significant difference was seen between diagnostic laparoscopy and laparotomy. There was no significant difference in the distribution of visceral adhesions after laparoscopic fundoplication (six liver and stomach, three liver/stomach and omentum) and open fundoplication (23 and six respectively). However, a significant difference in adhesion formation involving intestine (liver, stomach, bowel) between laparoscopic fundoplication (11 of 21) and open fundoplication (30 of 34) was found ($P < 0{\cdot}05$).

Thickness of adhesions. The thickness of adhesions after laparoscopic and open fundoplication was significantly different ($P < 0{\cdot}05$) and inversely proportional. Animals that had laparoscopic surgery (laparoscopic fundoplication and diagnostic laparoscopy) mostly developed adhesions less than 3 mm thick (12 of 21 and three of five respectively), whereas those that had open surgery (open fundoplication and diagnostic laparotomy) mostly developed adhesions more than 5 mm thick (*Table 2*).

Tenacity. Animals that had a laparoscopic intervention mostly developed type I and II adhesions (12 of 21 after laparoscopic fundoplication and all five after diagnostic laparoscopy respectively), whereas open surgery was followed mainly by the development of type III adhesions (28 of 34 after fundoplication and four of six after diagnostic laparotomy) (*Table 2*). A small number of type I adhesions was noticed in all groups. Only type II adhesions developed after diagnostic laparoscopy. There were significant differences between open and laparoscopic surgery (laparoscopic *versus* open fundoplication, $P < 0{\cdot}01$; open fundoplication *versus* diagnostic laparoscopy, $P < 0{\cdot}05$).

Vascularization of adhesions. All animals primarily developed vascularized adhesions. However, after laparoscopic and open fundoplication one-fifth and one-quarter of the adhesions respectively were avascularized. All the adhesions that developed after diagnostic laparoscopy were vascularized, whereas half of those that developed after diagnostic laparotomy were avascularized. There were no significant differences between all the groups investigated. Overall adhesion score[23] is summarized in *Fig. 1*.

Tumour necrosis factor concentrations

There were different TNF-α ranges in the fundoplication groups (*Fig. 2*). Laparoscopic fundoplication induced an early intraoperative peak of TNF-α secretion in plasma and the preoperative level was reached 24 h after surgery. Open fundoplication induced only a slight rise in TNF-α secretion at operation and 1 h after operation; the peak

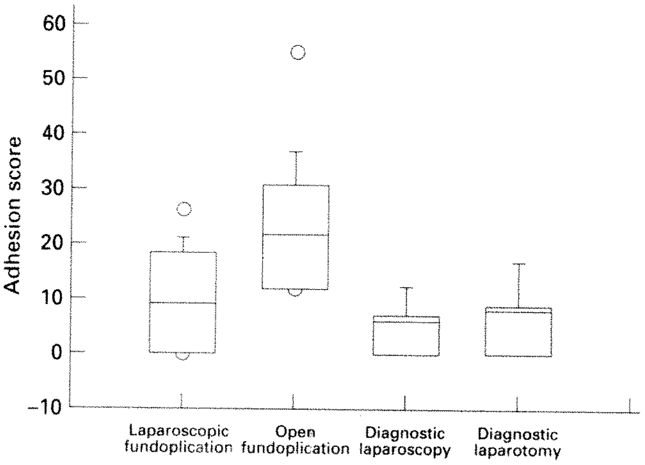

Fig. 1 Total adhesion scores in the four surgical groups. Boxes include values between the 5th and 95th percentile with the median values (horizontal line). T bars indicate standard deviations. Values outside the standard deviation are indicated as open circles. The adhesion score was significantly higher after open fundoplication than after the other procedures ($P < 0{\cdot}01$, unpaired t test)

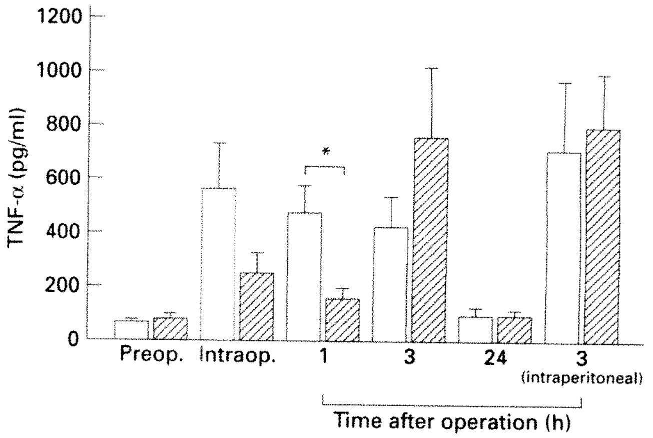

Fig. 2 Plasma and intraperitoneal tumour necrosis factor (TNF) α levels following laparoscopic (□) or open (▨) fundoplication. Values are mean(s.e.m.) $^{*}P < 0{\cdot}05$, unpaired t test

TNF-α level occurred 3 h after operation. Some 24 h after surgery, the TNF-α level had again reached preoperative levels. TNF-α secretion was significantly different between laparoscopic and open fundoplication groups ($P < 0{\cdot}05$) 1 h after surgery, whereas all other plasma TNF-α values for the two fundoplication groups showed no significant differences. TNF-α concentrations, measured 3 h after operation in the peritoneal fluid, were increased after open fundoplication compared with laparoscopic fundoplication (*P* not significant). Comparison of peritoneal TNF-α concentrations with adhesion tenacity showed that no adhesions developed with TNF-α levels of 200 pg/ml or less.

Discussion

The present study demonstrates that laparoscopic and open Nissen fundoplication are technically feasible in the rat model and that a different extent (more after open surgery) and type of adhesion formation between laparoscopic fundoplication (parietal) and open fundoplication (visceral) are induced.

The development of peritoneal adhesions is an inevitable outcome of surgical operations in the abdominal cavity. It is one of the main complications, occurring some weeks or months after the initial operation[17], and it results in morbidity following abdominal, gynaecological, or cardiac surgical procedures. Such complications are visceral dysfunction, chronic abdominal pain, infertility and early or delayed bowel obstruction[10,14,15,23]. Morbidity due to adhesion formation is associated with increased socioeconomic costs, which reach up to $1.18 million in the USA per year[12]. Menzies and Ellis[14] published a prospective trial of 210 patients with a history of previous abdominal surgery who underwent a 'second-time' laparotomy; peritoneal adhesions were found in 93 per cent. Furthermore, in 115 patients who underwent first-time laparotomy, abdominal adhesions were demonstrated in 10 per cent.

Multiple factors may be responsible for the development of postoperative adhesions, for example the extent of surgical trauma and length of the procedure, bacterial contamination, allergic reactions to inserted foreign bodies and tissue ischaemia[17]. All of these factors cause peritoneal tissue injury, which leads to an inflammatory reaction and cytokine release, which are considered to be trigger mechanisms for further adhesion development. Thus, mesothelial, inflammatory and endothelial cells are activated to produce and release plasminogen activator inhibitors 1 and 2, which predispose to the loss of plasminogen activation in the injured area of the peritoneum. This process leads to impairment of fibrinolysis, fibrin coagulation and fibrin matrix formation[17,24,25].

Kaidi *et al.*[20,21] found a direct correlation between the grade of injury, TNF-α secretion and the extent of peritoneal adhesion formation. In the present series, during laparoscopic fundoplication there was a rapid rise in plasma TNF-α level, reaching its peak at operation and gradually decreasing to preoperative levels by 24 h after surgery. In contrast, there was only a slight TNF-α rise during and 1 h after open surgery, with a peak level 3 h after surgery. Again 24 h after surgery TNF-α levels were the same as those before operation. The overall TNF-α concentrations in the peritoneal fluid were higher than those in plasma 3 h after surgery and were slightly increased following open surgery (*P* not significant). These findings suggest that TNF-α may be produced primarily in the peritoneal cavity, secreted into the operative field and afterwards absorbed into the systemic circulation. This means that the TNF-α produced during the open procedure may well have been lost externally (open cavity, rinsing), and this may explain the fact that TNF-α levels were reduced during open fundoplication and 1 h afterwards. It also explains why no correlation between TNF-α levels and tenacity of adhesion formation was found and that any assessment of TNF as a measure of inflammatory response in the peritoneum may be inappropriate. A similar tendency was observed in other series which investigated the inflammatory cytokine response following abdominal surgical procedures[22].

No adhesions were detected in the abdominal cavity following intraperitoneal anaesthesia and skin incision, which suggests that surgical trauma alone without opening the peritoneal cavity is not responsible for adhesion development ($n = 7$; data not shown). A minimal surgical trauma, such as diagnostic laparoscopy or diagnostic laparotomy without further surgical intervention or bowel revision, leads to less adhesion formation than upper gastrointestinal surgery. Laparoscopic Nissen fundoplication leads to less postoperative adhesion formation than the open procedure. Furthermore, adhesions in the laparoscopic group were of the parietal type, from omentum or small bowel to the parietal peritoneum, rather than the visceral type, developed between the abdominal organs themselves.

Similar observations were published by Tittel *et al.*[26] in a canine model, and by Semm[27] in humans. Semm clearly demonstrated in women who underwent diagnostic laparoscopy after previous abdominal operations (open or laparoscopic) that 84 per cent had adhesion formation after open surgery whereas only 40 per cent did after laparoscopic intervention. However, in his series it remained unclear which type of adhesions was responsible for the development of postoperative complications.

In conclusion, the present study demonstrates that laparoscopic surgery is technically feasible in the rat model with low morbidity and mortality rates at long-term follow-up. Postoperative adhesion formation occurred more frequently and severely after open surgery compared with the same operation performed laparoscopically. The TNF-α levels measured intraperitoneally did not differ between the two groups, and a positive correlation between the tenacity of adhesion formation and the intraperitoneal TNF-α level was not found. This animal model can be used for laparoscopic surgery and the study of adhesion formation. However, further studies are needed to evaluate the pathophysiological changes leading to postoperative adhesion formation and its prevention.

Background Stage migration in gastric cancer confounds establishment of standard treatment according to stage.

Methods To determine how closely lymph nodes should be examined to report correct staging, 402 node-positive patients were evaluated retrospectively. A total of 23 233 lymph nodes were reviewed histologically and their maximum dimension was measured. Another 254 nodes from 12 patients were used to evaluate shrinkage after fixation and preparation of the histological slide.

Results Metastasis was detected in 3142 nodes, 1163 with well differentiated tumours (WDTs) and 1979 with poorly differentiated tumours (PDTs). Mean(s.d.) size of metastatic nodes was 7·80(5·08) mm in all, 8·44(5·74) mm in WDTs and 7·42(4·62) mm in PDTs. Both positive and negative nodes shrank between 10 and 20 per cent during histological processing. If all nodes 5 mm or less in size when fixed are ignored 37·8 per cent of all metastatic nodes will be missed. Downstaging will occur in 14·9 per cent and 4·2 per cent of the cases if all nodes less than 6 and 4 mm respectively are ignored.

Conclusion To keep the rate of stage migration caused by this factor below 5 per cent, all lymph nodes 4 mm or more in size (5 mm when fresh) should be retrieved and examined.

In the treatment of malignant disease, the selection of primary or adjuvant treatment is often decided by stage. Evaluation of new treatments and comparison of outcomes in different countries are possible only if a common stage system is properly applied. In most solid tumours, the tumour node metastasis (TNM) classification of the Union Internacional Contra la Cancrum (UICC) is the most commonly used classification. Because the pTNM closely correlates with prognosis, it is often included in clinical trial protocols. Stage migration can occur easily in any category of TNM[2], especially in N or pN stage, for several reasons including more extended nodal dissection, retrieving more nodes from the specimen or more sectioning of each node[3]. Stage migration caused by extended surgery has been discussed extensively[4], but the other two factors have not yet been well evaluated for gastric cancer, although clinical practice among pathologists varies enormously from country to country. In Japan lymph nodes are retrieved from the fresh *en bloc* specimen by surgeons and as many nodes as possible are examined by pathologists. In many western countries, it is the pathologists who retrieve nodes and examine them. The number examined per specimen varies between countries and between pathologists[5]. Among the various factors influencing lymph node retrieval, this study focused on the size, as this seems to be one of the most important factors and other factors are difficult to assess objectively. To minimize stage migration it is important to know how many nodes should be examined and whether small nodes can be ignored. In this study, the relationship between metastatic state and nodal size was studied to determine the impact of ignoring small nodes on stage migration in patients with gastric cancer.

Patients and methods

A total of 1741 patients underwent gastric resection for gastric carcinoma between 1986 and 1991. Some 427 patients treated with curative intent were node positive, of which 402 were included in this study, while 25 were excluded because of insufficient data.

Immediately following D_2 (level 1 and 2 lymphadenectomy) or more extended gastrectomy all lymph nodes that were detectable by sight and palpation and attached to the resected specimen were retrieved by surgeons. Lymph nodes were divided into groups by their station according to the Japanese Classification of Gastric Carcinoma[6]. They were fixed in 10 per cent formalin solution and processed for pathological investigation. Lymph nodes were cut in two through the hilum along the long axis and embedded in paraffin. Nodes of 3 mm or less were embedded in paraffin whole. Sections measuring 3 μm in thickness were obtained from each paraffin block and stained with haematoxylin and eosin. This procedure is known to cause a reduction in the size of lymph nodes. The reduction rate was calculated by measuring a further 254 lymph nodes from 12 patients before and after the procedure.

All lymph nodes were examined for metastases and the size of each lymph node was measured on the glass slide. Metastatic lymph nodes were also divided into two groups by the level of differentiation of the primary tumour: WDT included well and moderately differentiated tubular adenocarcinoma and papillary adenocarcinoma, and PDT included poorly differentiated adenocarcinoma, signet-ring cell carcinoma and mucinous adenocarcinoma. The size of lymph nodes was evaluated in relation to metastatic state and the histological type of the primary tumour.

Lymph node data, i.e. location, size, metastatic state and histological type, were recorded for every lymph node of each patient and the pN stage was determined according to the Japanese Classification of Gastric Carcinoma[6]. Downstaging that would be

Paper accepted 6 October 1997

caused by ignoring all nodes smaller than a certain size was calculated.

Statistical analysis of shrinkage rate and lymph node size were carried out using Wilcoxon's rank sum score test; other analyses on the 23 233 nodes were performed using analysis of variance.

Results

Shrinkage rate

Of 254 lymph nodes, 25 were metastatic and the rest were non-metastatic. The mean relative size after the process of preparing glass slides was 0·84 (fresh size 1·0) and the shrinkage rate was thus 16 per cent. There was no significant difference in shrinkage rate between metastatic and non-metastatic lymph nodes at any size (*Table 1*). The shrinkage rate was smallest with nodes of 5 mm or less and greatest between 6 and 10 mm, irrespective of metastatic state.

Size of lymph node and stage migration

A total of 23 233 lymph nodes in 402 patients were examined. The mean number of retrieved nodes was 57·8 per resected specimen. Mean(s.d.) size was 5·64(3·40) mm. Modal size of the lymph nodes was 3 mm (14·9 per cent) and 63·8 per cent of all lymph nodes ranged from 2 to 6 mm.

Mean(s.d.) size of the metastatic lymph nodes was 7·80(5·08) mm, while that of non-metastatic nodes was 5·30(3·05) mm ($P < 0{\cdot}0001$) (*Fig. 1*). If all lymph nodes less than 5 mm in size had been ignored, 26·4 per cent of all metastatic nodes would have been missed. Similarly 37·8 and 73·0 per cent of involved nodes would have been missed if nodes smaller than 6 and 10 mm respectively had been ignored.

Among the metastatic lymph nodes, a significant difference in the mean size was seen between the WDT and PDT groups (*Table 2*).

Table 1 Mean(s.d.) relative size of lymph nodes after fixation and preparation of glass slides (size in fresh state 1·0)

Size (mm)	Metastatic lymph nodes	Non-metastatic lymph nodes	Total

Table 3 Incidence of stage migration by ignoring small nodes

	Size of lymph node ignored (mm)				
	1–2	1–3	1–4	1–5	1–9
Stage migration (n)	6 (1·5)	17 (4·2)	31 (7·7)	60 (14·9)	167 (41·5)
Shift to pN_0 (n)	5 (1·2)	15 (3·7)	25 (6·2)	48 (11·9)	112 (27·9)

Values in parentheses are percentages

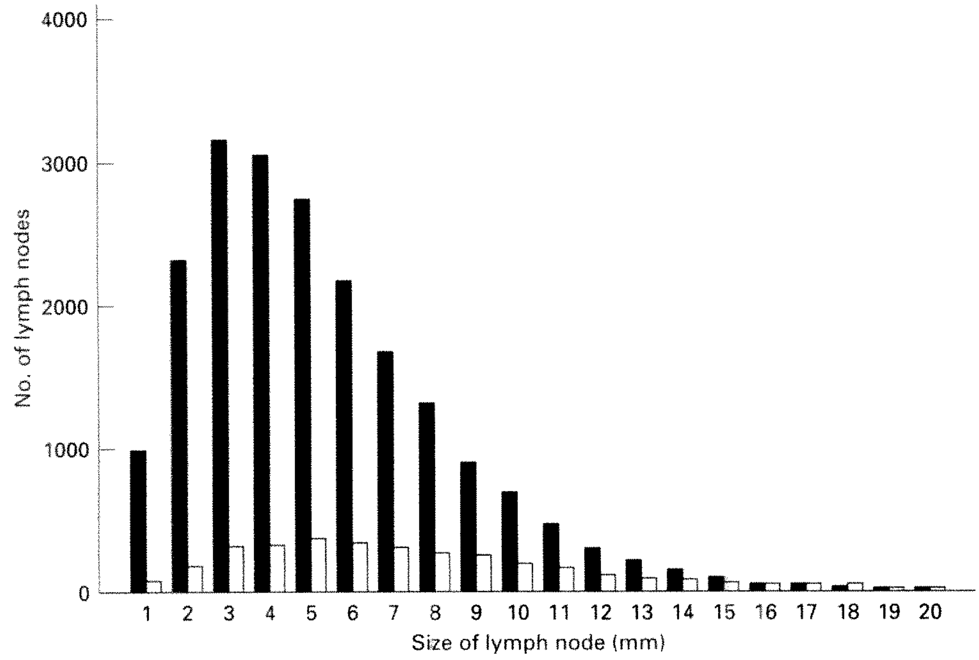

Fig. 1 Size distribution of metastatic (□) and non-metastatic (■) lymph nodes

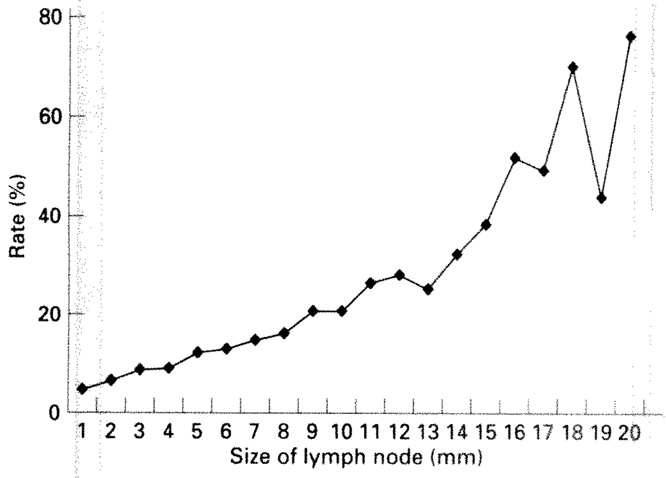

Fig. 2 Rate of metastatic nodes according to the size of lymph nodes

The proportion of positive nodes increased with the size of lymph nodes (*Fig. 2*). Only 5 per cent of 1-mm lymph nodes were metastatic, whereas 12 per cent of 5-mm and 21 per cent of 10-mm nodes had metastases.

The number of patients who would be downstaged if small nodes were ignored was calculated, as was the percentage of cases in which downstaging to pN_0 occurred (*Table 3*).

Discussion

TNM classification is not simply an instrument to assist in the prognosis, it also provides essential information on the basis of which the physician can plan treatment. Hammond and Henson[7] emphasized the important role of pathologists in the management of patients with cancer. Several methods have been described for obtaining accurate staging of lymphatic spread; some aimed at better retrieval of nodes and others at better detection of the microfoci of metastasis. The fat clearance method resulted in 7 per cent upstaging in 41 patients with colorectal cancer[8], and 29 per cent upstaging in 11 patients with gastric cancer[9]. It certainly provides more accurate pN stage information but is too labour-intensive for routine use in clinical practice. Serial sectioning and immunostaining are possible methods for detecting micrometastases but it is impracticable to carry out complete serial sectioning of all lymph nodes. In a theoretical evaluation Wilkinson and Hause[10] predicted a detection rate of 0·5 mm foci in 5-mm nodes of 16 per cent by a single central section but up to about 40 per cent by using three sections, the central and two quarter sections, with the assumption that each node contains only one micrometastatic focus. When Natsugoe *et al.*[11] compared making four sections from each node with the conventional one section method, only four of 304 nodes in patients with gastric cancer had micrometastatic foci that were not detected by the conventional method. More than one-half of these microfoci were less than a maximum of 0·5 mm in dimension. The theoretical evaluation of Wilkinson and Hause[10] does not, therefore, reflect reality, and any realistic practical method of node examination seems unlikely to have an impact on stage migration.

Several authors have reported the usefulness of immunostaining using antibodies to keratin or carcinoembryonic antigen for colorectal carcinomas[8,12,13]. According to these authors, about 5 per cent more metastatic nodes were found and stage shift occurred in about 30 per cent of patients with colorectal carcinoma. Recently, Siewert *et al.*[14] reported a high detection rate (90 per cent) of individual cancer cells in patients with pN_0 by using antibodies to human cytokeratins, but the clinical implication and prognostic significance of these 'individual tumour cells' detected in lymph nodes are still uncertain. Such cancer cells are nominated as 'micro involvement' to distinguish them from 'micrometastasis' which is defined as a tumour nest having a stromal reaction. Routine use of these methods would double or triple the workload of preparing slides because double staining is not acceptable. Recently Hayashi *et al.*[15] reported the efficacy of genetic diagnosis of lymph node metastasis in colorectal cancer. This method can detect micrometastasis at the level of an individual cell, but is available only for tumours that have a genetic mutation suitable for polymerase chain reaction detection. Because of the lower rate of specific gene abnormality in gastric cancer and greater genetic heterogeneity than in colorectal cancer, this technique seems to be of little value for gastric cancer at present[16,17].

The methods that increase the detection rate of micrometastasis can be effective only when reasonable numbers of nodes are retrieved. Retrieving small nodes does not require any special technique, but diligence and time. It may be more difficult to retrieve sufficient numbers of small nodes from western patients, who generally have higher levels of body fat than Japanese, but from personal experience (M.S.) it is possible to retrieve an average of 60 nodes per specimen, which is equivalent to the number reported in this paper[18].

The mean size of metastatic nodes of WDT is significantly larger than that of PDT, but more than one-third of metastatic nodes in the former are smaller than 6 mm. Therefore the principles of retrieval should be applied irrespective of histological type of primary tumour.

Although retrieving many small apparently normal nodes is laborious, it remains much more feasible than the fat clearance method. Moreover, Bunt *et al.*[18] have suggested that retrieving from a fresh specimen might be more accurate than the fat clearance method if performed by an experienced surgeon, and that it can be as good as the fat clearance method if done by ordinary pathologists. The present data showed that 37·8 per cent of metastatic nodes were 5 mm or less in diameter. At this size, the shrinkage rate is about 10 per cent and the size evaluated on the glass slides is almost the same as that in the fresh state. If all of these nodes are ignored, stage migration will occur in 14·9 per cent of cases, among which 11·9 per cent will be downstaged to pN_0. In one study[9], the mean number of retrieved nodes using conventional methods was only 17·7 per specimen, which is 18·5 smaller than the mean number yielded by the fat clearance method. In the Dutch Gastric Cancer Trial[18] it was reported that the number of retrieved nodes was ten or fewer in 43 of 113 cases (38 per cent) treated by limited surgery and 20 or fewer in 43 of 114 (38 per cent) treated by D_2 gastrectomy. Ten or 20 is a much smaller number of lymph nodes than the expected average from a gastrectomy specimen of respective type[18]. The lack of diligence implied by these figures reflects the generally poor understanding of the impact of ignoring small nodes on stage migration. The best surgical treatment and adjuvant therapy for gastric cancer is still the subject of clinical trials[19,20]. Failure to establish the gold standard is partly a result of a lack of stratification by stage in these trials. Pathologists should be fully aware of the importance of exact staging and their role in establishing the stage specific treatment of choice.

Background A clinicopathological study of early gastric cancer with submucosal invasion was carried out in relation to lymph node metastasis.

Methods A retrospective study was conducted of 245 patients with submucosal gastric cancer treated by gastrectomy combined with D_2 lymph node resection between 1985 and 1994 in a university hospital.

Results Lymph node metastasis was observed in 34 patients (14 per cent). The mortality rate due to recurrence in patients with lymph node metastasis (three of 34) was significantly higher than in those without lymph node metastasis (five (2 per cent) of 211) ($\chi^2 = 3{\cdot}95$, 1 d.f., $P < 0{\cdot}05$). Tumour size, depth of invasion, lymphatic involvement of cancer cells and preoperative diagnosis of advanced cancer correlated significantly with the presence of lymph node metastasis. When the submucosal carcinomas were classified into three categories according to depth of invasion by dividing the submucosal (sm) layer into three equal parts, sm1, sm2 and sm3, the incidence of lymph node metastasis increased from 2 per cent to 12 and 20 per cent respectively.

Conclusion When the pathological report reveals sm1 invasion after laparoscopic or endoscopic surgery, reoperation should not be necessary because sm1-carcinomas with diameters of less than 2 cm do not usually metastasize to the lymph nodes.

Recent progress in the diagnosis and surgical treatment of early gastric cancer has reduced the mortality rate associated with gastric cancer markedly, particularly as a result of improved early diagnosis of asymptomatic early gastric cancer[1]. In Japan, patients with early gastric cancer have a favourable prognosis after curative surgery with reported 5-year survival rates in excess of 90 per cent[2–5]. However, although early gastric carcinoma is potentially highly curable by surgical treatment, about 10 per cent of patients suffer recurrence after 'curative' operations for this cancer[6]. As such patients will survive for long periods, more attention should be focused on the relief of symptoms to improve the quality of life. In the authors' hospital, gastrectomy with D_2 lymph node dissection was the standard procedure for early gastric cancer until 1976. Gastrectomy with D_1 and no. 7 lymph node dissection was introduced for mucosal cancer in 1977, endoscopic mucosal resection was commenced in 1990, and laparoscopic surgery for mucosal cancer was instituted in 1992[7–10].

In this study, patients with early gastric cancer with submucosal invasion (sm-carcinoma) were investigated clinicopathologically in relation to the depth of invasion in the submucosal layer and lymph node metastasis, in order to establish the most appropriate treatment for sm-carcinoma.

Patients and methods

From 1985 to 1994, 245 patients with sm-carcinoma and no evidence of any other malignancy underwent gastrectomy with D_2 lymph node resection. All the cancers were diagnosed histopathologically as sm-carcinomas. The postoperative follow-up study was conducted in April 1995, when the cumulative mortality rate due to recurrence was calculated and the factors involved in death due to sm-carcinoma were investigated.

The clinicopathological study was based on the Japanese Classification of Gastric Carcinoma of the Japanese Research Society for Gastric Cancer[11]. Preoperative diagnoses were made on the basis of endoscopic and radiological findings, surgical specimens were reviewed by the chief surgeon when the operation was performed, and all pathological slides were reviewed by experienced pathologists in the authors' hospital. The macroscopic features of each gastric cancer were classified in terms of tumour location, macroscopic type and size. Microscopic features were classified according to histological type, infiltration pattern, tumour growth into the surrounding tissue, depth of invasion, lymphatic invasion, venous invasion and lymph node metastasis. Furthermore, submucosal invasion depth was divided into three categories, sm1, sm2 and sm3, by dividing the submucosal layer into three equal parts. All slides were submitted 'blindly' with respect to nodal status to the pathologists for determination of submucosal involvement. The recurrence pattern was determined by reviewing the medical records, including physical examination, laboratory data, ultrasonography and computed tomography findings.

Statistical analysis

The χ^2 test or Student's t test, as appropriate, was used for statistical analysis. The Kaplan–Meier method was used to estimate survival rates, and differences between them were assessed with the log rank test. Logistic regression analysis was used to evaluate risk factors for lymph node metastasis, with Cox's proportional hazards analysis to evaluate survival, using SAS software (SAS Institute, Cary, North Carolina, USA)[12,13]. $P < 0{\cdot}05$ was considered statistically significant.

Results

The clinicopathological findings are summarized in *Tables 1* and *2*. A total of 245 patients had early gastric cancer

Advanced gastric cancer was diagnosed before operation in 16 patients, five of whom had lymph node metastasis (*Table 2*), whereas 29 (3 per cent) of the 229 who were diagnosed before operation as having early gastric cancer had lymph node metastasis; these values were significantly different ($\chi^2 = 4{\cdot}32$, 1 d.f., $P < 0{\cdot}05$) (*Table 2*).

In patients with sm-carcinoma with lymph node metastasis, the incidence of lymphatic involvement was higher than in those without lymph node metastasis, but the incidence of venous involvement in these two groups did not differ significantly (*Table 2*).

Table 3 shows the incidence of lymph node metastasis according to the subdivision of submucosal invasion and lymph node metastasis. When lymph node metastasis was subcategorized from n1 to n4, no significant correlation

sm, Submucosal. *$\chi^2 = 8{\cdot}61$, 1 d.f., $P < 0{\cdot}01$ *versus* sm2 and sm3; †$\chi^2 = 8{\cdot}19$, 1 d.f., $P < 0{\cdot}01$ *versus* sm1 and sm2; ‡$\chi^2 = 34{\cdot}59$, 3 d.f., $P < 0{\cdot}01$

between submucosal invasion and the extent of lymph node metastasis was found.

The incidence of lymph node metastasis in patients with sm1, sm2 and sm3 carcinomas was 2, 12 and 20 per cent respectively (*Table 3*). Metastasis was significantly more common in sm3-carcinoma than in sm1- and sm2-carcinoma (*Table 3*). Only one patient with sm1-carcinoma had lymph node metastasis (the primary tumour was 5·5 cm in diameter) and n3 and n4 lymph node metastases were found only in patients with sm3-carcinoma (*Table 3*).

The mean(s.d.) diameter of lesions with lymph node metastasis was significantly greater than that of those without lymph node metastasis (*Table 2*). Lesions were classified into four groups according to diameter and there was a progressive increase in nodal metastasis with increasing size (*Table 3*).

Eight patients with sm-carcinoma died from recurrence during the observation period, significantly more in the node-positive group (*Table 1*). As all the patients who died had sm3 invasion, sm3-carcinoma was thought to be the most important risk factor for death from recurrent carcinoma. Overall survival rates according to the subcategory of invasion depth are shown in *Fig. 1*. Patients with sm1-carcinoma showed a significant survival benefit compared with those with sm3-carcinoma ($P < 0{\cdot}05$).

The survival rates of the patients with and without lymph node metastasis did not differ significantly (*Fig. 2*). Multivariate analysis was performed using logistic regression analysis and Cox proportional hazards analysis. The independent risk factors for lymph node metastasis were large tumour size and the degree of submucosal involvement, as shown in *Table 4*. The risk of the lymph node metastasis of sm2- and sm3-carcinomas was higher than that of sm1-carcinoma ($P = 0{\cdot}02$, odds ratio 11·262). The independent prognostic effect of six factors for survival was evaluated by Cox's proportional hazards analysis as shown in *Table 5*. The important factors for survival were submucosal involvement, vascular involvement and age.

Discussion

In Japan the prognosis of patients with early gastric cancer is very favourable after curative gastrectomy with lymph node dissection. Reported 5-year survival rates exceed 90 per cent[2–5]. However, lymph node metastasis, large tumours, submucosal invasion and lymphatic involvement of cancer cells remain risk factors for recurrence of early gastric cancer[9,14–22]. Recently, 'non-gastrectomy' procedures have been performed for small mucosal gastric cancer (m-carcinoma), including endoscopic mucosal resection and laparoscopic surgery[23,24]. In the authors' institution, laparoscopic surgery is indicated for type IIa cancers smaller than 2·5 cm in diameter and type IIc cancers of less than 1·5 cm without ulceration, and endoscopic mucosal resection is carried out for tumours smaller than 1 cm in diameter without ulcer scars[9,10]. To select the most appropriate operative procedures for mucosal gastric cancer, the depth of cancer invasion must be evaluated before operation using flexible endoscopy and gastrointestinal radiography. In addition, the introduction of endoscopic ultrasonography with a 20-MHz sonoprobe system[25] has increased diagnostic accuracy, as it enables mucosal and submucosal invasion by early gastric cancer to be differentiated. Such precise preoperative diagnostic methods will result in improved quality of life for these patients without reducing curability.

At present, the standard treatment in the authors' institution for sm-carcinoma is radical gastrectomy with

Table 4 Logistic regression analysis for factors associated with lymph node metastasis in early gastric cancer with submucosal invasion

D_2 lymph node dissection[8,26,27]. If sm-carcinomas without lymph node metastasis could be identified before operation, the indications for local resection could possibly be extended to some subcategories of sm-carcinoma. In this study the clinicopathological features of sm-carcinoma in relation to lymph node metastasis and prognosis were investigated.

Initially, the risk factors for lymph node metastasis of early gastric cancer with submucosal invasion were analysed, because the most important factor related to the prognosis associated with sm-carcinoma appears to be lymph node metastasis. Using univariate and multivariate analysis, high-risk factors for lymph node metastasis of sm-carcinoma were found to be large tumours and deep invasion. Furthermore, important factors for survival using Cox's proportional hazards model were the degree of submucosal involvement, vascular involvement and age. Hioki *et al.*[23] found that lymph node metastasis was common in patients with submucosal or elevated early gastric cancer, particularly if the lesion diameter exceeded 4 cm. Boku *et al.*[28] reported that lymph node metastasis occurred more frequently with protruded-type cancer with a diameter greater than 3 cm and submucosal invasion. Maehara *et al.*[14] reported that independent risk factors for the occurrence of lymph node metastasis included large tumours, submucosal invasion and lymphatic involvement by tumour cells.

When sm-carcinomas were classified into three groups by dividing the submucosal layer into three equal parts (sm1, sm2 and sm3), lymph node metastasis in the sm1 layer was limited to level 1, although 11 of 26 metastases in the sm3 layer were at more than level 2. When the sm-carcinomas were classified into four groups according to diameter, the incidence of metastases increased significantly depending on the lesion size. These findings suggest that patients with sm-carcinoma invading to the depth of sm1 and with a diameter of 2 cm or less could be treated by modified radical gastrectomy, although those with sm3 layer invasion should undergo standard radical gastrectomy with D_2 dissection of lymph nodes.

Recently, the accuracy of preoperative diagnosis of the depth of cancer invasion has improved, owing to the widespread use of endoscopic ultrasonography in Japan, and m- and sm-carcinomas can now be differentiated[25,29,30]. With a 20-MHz sonoprobe system the diagnostic accuracy in differentiating mucosal and submucosal invasion has increased to 88·9 per cent[25].

However, because it is difficult to determine the sm-carcinoma subclass before operation, the authors suggest performing standard gastrectomy with D_2 lymph node dissection for patients with a preoperative diagnosis of sm-carcinoma. In addition, as patients with large sm3-carcinomas are at high risk for developing level 2 lymph node metastasis, adjuvant chemotherapy may be indicated for such patients. However, it should not be necessary to reoperate on patients if the pathological reports reveal sm1-carcinoma after they have been treated with laparoscopic or endoscopic surgery.

Preoperative risk analysis and postoperative mortality of oesophagectomy for resectable oesophageal cancer

H. BARTELS, H. J. STEIN and J. R. SIEWERT

Department of Surgery, Klinikum rechts der Isar der Technischen Universität München, München, Germany

Correspondence to: Dr H. Bartels, Chirurgische Klinik und Poliklink, Klinikum rechts der Isar der Technischen Universität München, Ismaningerstrasse 22, D-81 675 München, Germany

Background Postoperative mortality after oesophagectomy for oesophageal cancer depends largely on the preoperative physiological status of the patient.

Methods A composite scoring system to predict the risk of oesophagectomy based on objective preoperative parameters was developed based on a retrospective review of patients operated on and evaluated prospectively in two subsequent patient groups.

Results An initial retrospective multivariate analysis of 432 patients who had oesophagectomy identified a compromised general status ($P < 0{\cdot}001$) and poor cardiac ($P < 0{\cdot}001$), hepatic ($P < 0{\cdot}05$) and respiratory ($P < 0{\cdot}05$) function as independent predictors of a fatal postoperative course. Based on the relative risk associated with the individual impaired organ functions, a composite risk score was established. A prospective study in 121 patients confirmed that this composite scoring system provides a better identification of high-risk patients than any of the individual parameters. Inclusion of the composite score into the process of patient selection and choice of the procedure resulted in a decrease of postoperative mortality rate from 9·4 per cent (52 of 553) to 1·6 per cent (four of 252) ($P < 0{\cdot}001$).

Conclusion The risk of death after oesophagectomy for oesophageal cancer can be assessed objectively before surgery and quantified by a composite risk score. This score provides a useful tool for refining the criteria of patient selection for resection or the choice of procedure.

Despite recent advances with other therapeutic modalities, surgical resection provides the only chance of cure for patients with oesophageal carcinoma. For both squamous and adenocarcinoma of the oesophagus, the 5-year survival rate after complete surgical tumour resection (i.e. a Union Internacional Contra la Cancrum R_0 resection[1]) is of the order of 40 per cent in those who survive the procedure[2,3]. Oesophagectomy therefore remains the mainstay of therapy in patients with potentially resectable oesophageal cancer. Morbidity and mortality associated with oesophagectomy are, however, substantial. In a review of recent series the mean mortality rate from oesophagectomy for cancer was 13 per cent independent of the surgical approach[4] and even in experienced centres the postoperative mortality rate ranges between 5 and 10 per cent in the Western world[4].

Several analyses have shown that, after standardization of surgical resection and reconstruction techniques, the severity of the postoperative course and postoperative mortality depend largely on the preoperative physiological status of the patient[5,6]. The physiological status is, however, often markedly reduced in patients with oesophageal cancer. As hyperalimentation and other attempts to improve the general status of these patients before operation have failed to show any benefit[7,8], a reduction in the postoperative mortality rate can be achieved only by strict selection of patients who have adequate physiological reserve to withstand an extended surgical procedure and a potentially prolonged and complicated postoperative course.

None of the currently available scoring systems is applicable to the specific problems associated with oesophagectomy and reconstruction[9]. Most surgeons therefore rely on the 'impression' of the patient and their own 'experience' rather than objective parameters for the selection of patients for oesophagectomy. Nevertheless, in a recent consensus conference of the International Society for Diseases of the Esophagus held in August 1995 in Milan, all of the participating experts agreed on the importance of objective preoperative risk analysis to improve the outcome of surgical resection for oesophageal cancer[9]. In the present study an attempt was made to develop a composite scoring system which allows prediction of the risk of oesophagectomy for cancer based on objective preoperative physiological parameters. Three specific questions were addressed. (1) Can a detailed preoperative assessment identify individual physiological parameters (i.e. risk factors) that correlate with the postoperative course? (2) Can the risk for postoperative death after oesophagectomy be predicted with a risk score based on individual preoperative physiological parameters? (3) Can the clinical use of such a scoring system reduce the mortality rate of oesophagectomy?

Patients and methods

Patients

Between June 1982 and December 1996 a total of 805 patients with oesophageal cancer underwent oesophagectomy with curative intent. All patients had a detailed preoperative assessment of their general status, organ function and tumour stage according to the parameters listed in *Table 1*. All data from the preoperative assessment and postoperative course were documented prospectively in a database.

The mode and extent of resection were standardized and determined by the location and histological type of tumour as described elsewhere[2,3]. A radical transmediastinal resection with *en bloc* lymphadenectomy of the lower posterior mediastinum and upper abdomen (compartment II) was performed for

Paper accepted 22 September 1997

Table 1 Parameters used for preoperative functional assessment of patients with oesophageal cancer

- General status
  - Sex
  - Age
  - Karnofsky index[10] (0–100 per cent)
  - History of alcohol abuse ('yes' or 'no')
  - History of tobacco abuse ('yes' or 'no')
  - Weight loss (percentage of body-weight)
  - 'Mental cooperation' of the patient ('good' or 'poor')
- Pulmonary function
  - Vital capacity (percentage of normal)
  - Forced expiratory volume (FEV$_1$; percentage of normal)
  - Peak flow (percentage of normal)
  - P_{aO_2} (mmHg)
  - P_{aCO_2} (mmHg)
- Hepatic function
  - Serum albumin (g/dl)
  - Serum bilirubin (mg/l)
  - Partial thromboplastin time (s)
  - Aminopyrine breath test[11]
  - Cirrhosis ('yes' or 'no')
- Renal function
  - Creatinine clearance (ml/min)
- Cardiac function
  - Electrocardiogram ('abnormal' or 'normal')
  - Chest radiograph ('abnormal' or 'normal')
  - Cardiologist's evaluation with further detailed testing as indicated ('normal risk', 'increased risk' or 'high risk')
- Diabetes
  - 'Yes' or 'no'
- Tumour stage (based on standard staging techniques[12,13])
  - Locoregional (T$_1$ or T$_2$) or locally advanced (T$_3$ or T$_4$)

P_{aO_2}, arterial partial pressure of oxygen; P_{aCO_2}, arterial partial pressure of carbon dioxide

Table 2 Classification of the postoperative course

- Normal
  - Mechanical ventilation for less than 48 h
  - ICU treatment for less than 7 days
- Prolonged
  - Mechanical ventilation for 48 h to 7 days, or ICU treatment for 7–21 days
- Severe
  - Mechanical ventilation for more than 7 days, or ICU treatment for more than 21 days, or readmission to the ICU
- Fatal
  - Death within 30 days

ICU, intensive care unit

adenocarcinoma of the distal oesophagus, while a transthoracic *en bloc* resection with extended two-field lymphadenectomy was performed for squamous cell oesophageal cancer of the intrathoracic oesophagus. A gastric tube was used for reconstruction in 713 patients; transverse or left hemicolon was used for reconstruction in 84 patients. The oesophagointestinal anastomosis was performed in the neck in 756 of 805 patients. Patients with cervical oesophageal cancer and those who had resection with palliative intention were excluded from the study. The postoperative course was classified in each patient as defined in *Table 2*.

Study design

The study was performed in three phases. In phase I of the analysis each of the parameters documented before operation (*Table 1*) was correlated retrospectively to the severity of the postoperative course (*Table 2*) in 432 patients (377 men, 55 women; mean age 56·7 years) who had oesophagectomy between June 1982 and December 1991. Discriminant analysis was performed to select the best cut-off points for the parameters with an independent effect on multivariate analysis. Based on the established parameters, preoperative organ function was then estimated as 'normal', 'compromised' or 'severely impaired'. The impact of individual organ dysfunction on postoperative mortality was subsequently assessed by regression analysis and a composite score incorporating the weighted risk of each individual organ system for postoperative mortality was established.

In phase II of the analysis the clinical value of the composite risk score to predict postoperative mortality was assessed prospectively in 121 patients (106 men, 15 women; mean age 57·9 years) who had oesophagectomy for oesophageal cancer between January 1992 and December 1993. During phase I and phase II of the analysis, the decision to perform oesophagectomy was based solely on the judgement of the responsible surgeons. In December 1993 the results of phases I and II of the study were made known to all surgeons performing oesophagectomy.

From January 1994 to December 1996 (phase III of the study) the composite risk score of each patient was included in the decision-making process for selection for surgical resection and selection of the procedure. During this period patients with a high risk for postoperative death, based on the preoperative risk score, were referred for other modes of treatment or had oesophageal resection with two-stage reconstruction of the continuity of the alimentary tract (i.e. usually after 4 weeks). In the authors' experience, two-stage reconstruction is a safer way to perform oesophageal resection and reconstruction in high-risk patients (unpublished data). During this period oesophagectomy with primary reconstruction was performed in 211 patients (182 men, 29 women; mean age 58·4 years), and a delayed reconstruction after oesophagectomy was chosen in 41 patients (33 men, eight women; mean age 61·2 years). Non-surgical treatment modalities were used in 24 patients with potentially resectable oesophageal cancer but a high risk score on preoperative analysis.

Statistical analysis

All statistical analyses were performed with the BMDP (Los Angeles, California, USA) Statistical Software Package[14]. $P<0{\cdot}05$ was considered statistically significant.

Results

Multivariate analysis showed a significant correlation between the severity of the postoperative course and the preoperative Karnofsky index, the estimated mental 'cooperation' of the patient, vital capacity, arterial partial pressure of oxygen (P_{aO_2}), the aminopyrine breath test, the presence of cirrhosis, and an increased cardiac risk based on the cardiologist's judgement. The cut-off values that provided the best separation between a normal–prolonged and a severe–fatal postoperative course are shown in *Table 3*. Age, sex, tumour stage, presence of diabetes, renal function, and history of alcohol or tobacco abuse had no independent effect on the postoperative course.

Based on the established parameters, hepatic, cardiac and pulmonary function and the general status of the patient were classified individually as 'normal', 'compromised' or 'severely impaired' as shown in *Table 4*. Retrospective application of these organ scores to the 432 patients treated during phase I of the study (June 1982 to December 1991) confirmed a significantly increased postoperative mortality rate for patients with a severely impaired general status (relative risk 3·6, $P<0{\cdot}001$) followed by poor cardiac function (relative risk 2·8, $P<0{\cdot}001$), poor hepatic function (relative risk 2·1,

$P < 0\cdot05$) and impaired respiratory function (relative risk $1\cdot7$, $P < 0\cdot05$).

To create a composite risk score of all relevant parameters, a weighting factor was established based on the relative risk associated with each individual factor. This factor was: general status × 4, cardiac function × 3, hepatic function × 2 and respiratory function × 2. Multiplication of this weighting factor with the individual score for preoperative cardiac, hepatic and respiratory function and general status (*Table 4*), and summation of the results, creates a single composite score ranging between 11 total score points for a patient without any risk factors and 33 for a patient with the highest risk in all relevant parameters. Discriminant analysis showed that this composite scoring system provided a separation of patients into three distinct risk groups for postoperative mortality when applied to the group of patients from which it was derived. The postoperative 30-day mortality rate was $3\cdot6$ per cent in the 166 patients with 11–15 points ('low risk'), $8\cdot7$ per cent in the 194 with 16–21 score points ('moderate risk') and 28 per cent in the 72 with 22–33 score points ('high risk') ($P < 0\cdot05$ between all groups).

Table 3 Cut-off values for individual independent continuous parameters that provide the best separation between a normal–prolonged and a severe–fatal postoperative course after oesophagectomy (discriminant analysis in 432 patients undergoing oesophagectomy between June 1982 and December 1991)

	Parameter value	P*
Karnofsky index	80%	$< 0\cdot001$
Aminopyrine breath test	$0\cdot4$	$< 0\cdot05$
Vital capacity	90%	$< 0\cdot05$
P_{aO_2}	70 mmHg	$< 0\cdot05$

P_{aO_2}, arterial partial pressure of oxygen. *χ^2 test

Table 4 Classification of individual organ dysfunction based on multivariate analysis of the postoperative course after oesophagectomy

	Value or finding
Pulmonary function	
1 Normal	VC > 90% and P_{aO_2} > 70 mmHg
2 Compromised	VC < 90% or P_{aO_2} < 70 mmHg
3 Severely impaired	VC < 90% and P_{aO_2} < 70 mmHg
Hepatic function	
1 Normal	ABT > $0\cdot4$
2 Compromised	ABT < $0\cdot4$, no cirrhosis
3 Severely impaired	Cirrhosis
Cardiac function (based on cardiologist's impression)	
1 Normal	Normal risk for major surgical procedure
2 Compromised	Increased risk for major surgical procedure
3 Severely impaired	High-risk patient for major surgical procedure
General status	
1 Normal	Karnofsky index > 80% and 'good' cooperation
2 Compromised	Karnofsky index ≤ 80% or 'poor' cooperation
3 Severely impaired	Karnofsky index ≤ 80% and 'poor' cooperation

ABT, aminopyrine breath test; VC, vital capacity; P_{aO_2}, arterial partial pressure of oxygen

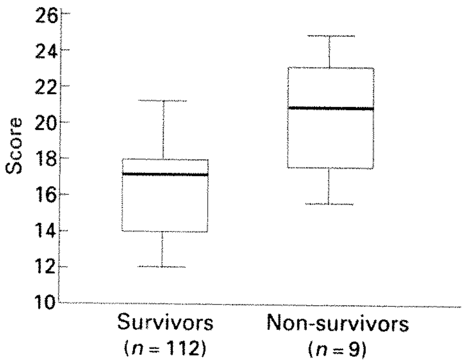

Fig. 1 Median and interquartile range of the composite risk score in 112 patients who survived oesophagectomy for cancer and in the nine who died within 30 days of the procedure during phase II of the study. $P < 0\cdot01$ (survivors *versus* non-survivors, Mann–Whitney U test). Whiskers indicate standard deviation

Prospective evaluation of this composite scoring system in 121 consecutive patients undergoing oesophagectomy for oesophageal cancer between January 1992 and December 1993 (phase II of the analysis) confirmed the validity of the scoring system in predicting the postoperative course. Postoperative 30-day mortality rate was 2 per cent in the 46 patients classified as 'low risk' (11–15 score points), 5 per cent in the 55 classified as 'moderate risk' (16–21 score points) and 25 per cent in the 20 classified as 'high risk' (22–33 score points; $P < 0\cdot01$ *versus* low risk and $P < 0\cdot05$ *versus* moderate risk). The median score value was 17 in 112 patients who survived the procedure compared with a median of 21 in the nine who died during the postoperative course ($P < 0\cdot01$) (*Fig. 1*). Of the nine patients who died after operation, five were classified as 'high risk' on preoperative assessment (risk score of 22 more).

Use of two-stage reconstruction in moderate and high-risk patients or complete exclusion of these patients from oesophagectomy (*Table 5*) resulted in a marked decrease in the postoperative mortality rate to below 2 per cent in this department after January 1994, although the

Table 5 Prevalence of one-stage surgery (resection and immediate reconstruction), two-stage surgery (resection and delayed reconstruction) and non-operative therapy in patients with potentially resectable oesophageal cancer in the various risk groups during phase III of the study, during which the composite risk score was included in the process of patient selection and choice of procedure

Risk group	No. of patients with 'one-stage' surgery	No. of patients with 'two-stage' surgery	No. of patients treated without operation
'Low risk' ($n = 111$)	111 (1)	0	0
'Moderate risk' ($n = 125$)	98 (1)	25 (1)	2
'High risk' ($n = 40$)	2	16 (1)	22
Total	211	41	24

Values in parentheses show patients who died after operation, giving a postoperative 30-day mortality rate of $1\cdot6$ per cent (four of 252 patients)

Table 6 Prevalence of 'high-risk' patients*, patients with locally advanced tumours (T_3 or T_4) and postoperative mortality from oesophagectomy for oesophageal cancer performed between 1982 and 1996

Time interval	Total no. of oesophageal resections	Prevalence of advanced tumours (T_3 or T_4)	Prevalence of 'high-risk' patients	Postoperative 30-day mortality	Postoperative 90-day mortality
Phase I					
June 1982 to December 1985	82	53 (65)	11 (13)	8 (10)	13 (16)
January 1986 to December 1987	121	73 (60·3)	22 (18·2)	13 (10·7)	20 (16·5)
January 1988 to December 1989	112	65 (58·0)	18 (16·1)	9 (8·0)	14 (12·5)
January 1990 to December 1991	117	72 (61·5)	21 (17·9)	13 (11·1)	19 (16·2)
Phase II					
January 1992 to December 1993	121	68 (56·2)	20 (16·5)	9 (7·4)	15 (12·4)
Phase III					
January 1994 to December 1995	163	97 (59·5)	12 (7·4)	3 (1·8)	8 (4·9)
January 1996 to December 1996	89	54 (61)	6 (7)	1 (1)	5 (6)

Values in parentheses are percentages. *Preoperative risk score of 22 or higher

prevalence of patients with advanced tumour stages remained unchanged (*Table 6*).

Discussion

Experience and training of the surgeon and the physiological status of the patient have been clearly identified as the main risk factors affecting the mortality rate after oesophagectomy for oesophageal cancer[5,6,9,15]. Postoperative mortality rates in experienced centres can be reduced further only by better selection of patients with sufficient physiological reserve to withstand the extended surgical procedure and a potentially complicated postoperative course. The present study shows that the risk of postoperative death in patients with resectable oesophageal cancer is determined in decreasing order by the preoperative general status, cardiac function, hepatic function and respiratory function. Objective assessment of preoperative function of these organ systems and calculation of a composite score based on the relative impact of each individual parameter allowed 'low', 'moderate' and 'high' risk groups for oesophageal resection to be established. This score thus provides an objective instrument for patient selection.

General status has been difficult to categorize objectively[5,9,16,17]. The estimation of the patient's mental 'cooperation' by the surgeon is undoubtedly subjective and introduces a non-quantifiable aspect into the proposed score. Attribution of 'poor' or 'good' cooperation alone, without other objective parameters, did not result in marked alteration of the total composite score.

Pulmonary and cardiac complications account for up to 70 per cent of postoperative deaths after oesophagectomy[5,16–20]. This is reflected in the rather high multiplier attributed to cardiac dysfunction in the composite score. A detailed cardiological evaluation is therefore recommended in any patient considered for oesophagectomy in whom the history, physical examination, standard electrocardiogram or chest radiograph show any abnormality. Spirometry has not been found consistently useful to predict pulmonary complications after major surgery[16,19]. The present and other analyses[5,21] show that the vital capacity in combination with P_{aO_2} allows identification of patients with an increased risk of postoperative death after oesophagectomy. Routine preoperative objective pulmonary function tests are therefore recommended before considering oesophagectomy.

Decompensated liver cirrhosis is considered a contraindication for oesophageal resection in many centres. An independent effect of hepatic dysfunction on the postoperative mortality rate is confirmed in the present study. This study shows that the aminopyrine breath test, which assesses hepatic cytochrome *P*450 function, allows identification of patients at increased risk of postoperative death even in the absence of frank cirrhosis[11]. This non-invasive and easy test should therefore be included in the assessment of hepatic function in any patient considered for oesophageal resection.

In contrast to other reports[5,6] tumour stage and patient age did not predict postoperative death in the present analysis. This is most likely because of the extensive preoperative tumour staging performed at this institution, which usually allowed identification and exclusion of patients with metastatic or irresectable tumours before operation. In contrast to other centres[5], palliative resection is not performed as less invasive palliative options are readily available. This study further shows that advanced age alone is not associated with an increased risk of postoperative death. Similar to the experience reported by Peracchia *et al.*[22], the present authors therefore believe that the benefits of potentially curative resection should not be withheld from an otherwise fit patient with a resectable tumour simply because of advanced age. Moreover, recent experience has shown that potentially curative resection in high-risk patient groups can be made safer by a two-stage procedure (oesophageal resection with delayed reconstruction of alimentary tract continuity). A similar experience with two-stage reconstruction in high-risk patients has been reported from Japan[23].

In summary, the present study shows that the risk of oesophagectomy in patients with potentially resectable oesophageal cancer can be assessed objectively before operation and quantified by a composite risk score. Strict inclusion of the risk score in the preoperative decision-making process resulted in a marked decrease of the postoperative mortality rate at this institution, to below 2 per cent. This risk score may therefore be used to refine the criteria of patient selection for resection or the choice of procedure.

Abdominal and dyspeptic symptoms in patients with peptic ulcer treated medically or surgically

R.-O. LINDSETMO, R. JOHNSEN* and A. REVHAUG

*Department of Surgery and *Institute of Community Medicine, Tromsø University Hospital, N-9038 Tromsø, Norway*
Correspondence to: Dr R.-O. Lindsetmo

Background Abdominal and dyspeptic complaints, which are prominent symptoms in patients with peptic ulceration, are commonly reported in the general population. There are few reports of follow-up study of peptic ulcer therapies in which clinical outcome has been compared with symptom reporting in community controls.

Methods Three populations of patients with peptic ulcer disease (patients who had elective proximal gastric vagotomy (PGV), those having PGV for emergency indications and those receiving medical treatment with H_2-receptor antagonists) were included in a questionnaire survey and compared with a group of randomly selected community controls.

Results The vagotomized patients reported fewer abdominal complaints ($P = 0\cdot0003$) and fewer dyspeptic complaints lasting for more than 1 week ($P = 0\cdot05$) than those treated medically. There was no significant difference between vagotomized patients and community controls in the reporting of abdominal ($P = 0\cdot2$) or dyspeptic ($P = 0\cdot9$) complaints.

Conclusion Taking abdominal complaints as the endpoint for former peptic ulcer treatment, surgical treatment with PGV seemed to be superior to therapy with H_2-receptor antagonists and produced an almost identical level of complaints to that seen in the community population.

Ulcer healing or recurrence has been the major endpoint in clinical trials evaluating peptic ulcer treatment. This has nowadays been more or less replaced by verified eradication of *Helicobacter pylori* infection, as removal of these bacteria from the gastric mucosa prevents ulcer recurrence[1,2]. There are surprisingly few reports comparing the long-term outcome of surgical and medical peptic ulcer treatment[3–7] using abdominal or dyspeptic complaints as clinical endpoints[8]. So far only one study[9] has incorporated abdominal complaints in healthy control subjects when investigating the clinical results following proximal gastric vagotomy (PGV). Patients after operation and those with peptic ulcer disease may have several reasons for dyspepsia. Treating the peptic ulcer disease may take away only one, or some, of several reasons for dyspeptic symptoms. For this reason, population controls should be mandatory when assessing clinical outcome of peptic ulcer treatment regimens. There appears to be no report contrasting the level of abdominal or dyspeptic complaints in medically or surgically treated patients with peptic ulceration with that of similar symptoms in the community population.

This study was designed to compare the long-term outcome in surgically or medically treated patients with peptic ulceration with that in a matched group of randomly selected non-ulcer subjects as a reference group using abdominal and dyspeptic complaints as the clinical endpoint.

Patients and methods

The study was performed as a postal questionnaire survey in three differently treated groups of patients with verified peptic ulcer disease. Patients who underwent PGV electively ($n = 368$) or as an emergency operation ($n = 130$) in the period from 1967 to 1990, and who were still alive on 1 January 1995, were identified from operating theatre records ($n = 721$). All those with peptic ulcers verified by endoscopic or radiological examination in the period from 1979 to 1986 and who had received only acid suppression medication were included as medically treated patients. From the National Population Register 762 healthy community controls were selected randomly and matched to the surgically treated patients for mean age and sex distribution.

All four groups received an identical questionnaire on abdominal complaints regarding type of abdominal discomfort or pain, its frequency and duration, consequences of the complaints on working ability, social life, quality of life and use of health services. The questionnaire also surveyed the patients' self-reported health condition, contemporary complaints or illnesses, family history of abdominal diseases, socioeconomic status, eating habits, consumption of coffee, tea, alcohol and drugs, and smoking.

Values are percentages (95 per cent confidence interval). *Only patients with paid employment were included. PGV, proximal gastric vagotomy

Those who did not answer within 1 month received a postal reminder. There was no financial gain or hint of health benefits associated with participation in the survey.

The questionnaire was composed of questions used previously in the Sørreisa gastrointestinal disorder study[10] and was constructed as described by Eypasch *et al.*[11]. Approximately 80 per cent (range 80·0–81·0 per cent) of patients in each group returned the questionnaire. After exclusion of those providing incomplete answers, reporting biliary disease now or previously, or having had any abdominal operation for reasons other than peptic ulceration, 193 elective and 75 emergency PGV responders, 134 medically treated patients and 322 community control responders were included in the final analysis.

Abdominal complaints were defined as the reporting of one or more of the following symptoms: abdominal pain or discomfort independent of localization or duration, heartburn, regurgitation, nausea, retching or borborygmia without bowel disturbances.

Dyspeptic complaints were defined as persistent or recurrent abdominal pain or discomfort centred in the upper abdomen. This definition was used to distinguish patients with mainly epigastric discomfort and pain as the main symptoms from those with heartburn as the main symptom[12]. By these definitions the entity 'dyspeptic complaints' represents a subgroup of the entity 'abdominal complaints'.

Bowel disturbances were defined as diarrhoea and/or constipation.

Table 5 Frequency of antiulcer drug use during follow-up among surgically or medically treated patients with peptic ulcer and in community controls

	Patients with peptic ulcer			
	Emergency PGV ($n = 75$)	Elective PGV ($n = 193$)	Medication ($n = 134$)	Controls ($n = 322$)
No drugs	76 (65–85)	65·3 (58·1–72·0)	37·3 (29·1–46·1)	72·7 (67·8–77·5)
Antacids	22 (13–33)	31·1 (24·6–38·2)	55·2 (46·4–63·8)	25·5 (20·7–30·2)
H_2-receptor antagonists*	10 (4–18)	19·9 (14·4–26·4)	39·6 (31·2–48·4)	4·0 (2·2–6·8)
Proton pump inhibitors†	3 (0–10)	4·4 (1·9–8·4)	5·2 (2·1–10·5)	0·6 (0·1–2·2)
Other‡	1 (0–7)	10·5 (6·6–15·8)	6·0 (2·6–11·4)	2·8 (1·3–5·2)

Values are percentages (95 per cent confidence interval). *Cimetidine, famotidine or ranitidine; †omeprazole or lansoprazole; ‡prescribed drugs such as sucralfate, anticholinergic agents, tricyclic antidepressant (trimipramine) or prokinetic agent (cisapride). PGV, proximal gastric vagotomy

Dumping syndrome was defined as dizziness and fatigue after meals.

Statistical analysis

The proportion of patients answering the different questions in the questionnaires was calculated as a percentage with 95 per cent confidence intervals based on a normal distribution. The χ^2 test with Yates' correction was applied when comparing dichotomous variables.

The calculations were performed using the microcomputer software Confidence Interval analysis (BMJ Publishing Group, London, UK)[13] and Epi Info 6 (WHO Shareware, Geneva, Switzerland)[14].

The study was approved by the Regional Committee for Medical Research Ethics and the Norwegian Social Science Data Services.

Results

The mean age of medically treated patients was 4·6 and 7·5 years lower than those operated on as an emergency and electively respectively. The age range in the control population was 47–75 years compared with 28–87 years in surgically treated patients. Mean age in the control group was close to that of the surgically treated groups, but the age range was smaller (*Table 1*).

Most of the emergency operations (64 per cent) were for massive ulcer bleeding; 36 per cent of patients had a vagotomy for perforated ulcer. Of these, 48 per cent had a duodenal ulcer and 52 per cent had a gastric ulcer. The distribution of ulcer type in the medical group was 44·0 per cent duodenal and 56·0 per cent gastric.

The proportion of patients reporting no complaints was significantly higher among the patients who had emergency or elective PGV than in medically treated patients ($P = 0·0003$) (*Table 2*). Vagotomized patients reported less abdominal pain at any location ($P = 0·0001$), fewer dyspeptic complaints lasting for more than 1 week ($P = 0·05$), less heartburn ($P < 0·0001$) and regurgitation ($P < 0·0001$), and fewer ulcer recurrences ($P = 0·05$) compared with medically treated patients. The proportion of vagotomized patients with no complaints or those with dyspeptic complaints were not significantly different from the proportion of subjects reporting no complaints or dyspeptic complaints in the community population ($P = 0·2$ and $P = 0·9$ respectively).

Approximately 40 per cent of patients with ulceration and healthy controls reported that they had suffered abdominal complaints lasting for more than 1 week. *Table 3* shows no significant differences between controls and patients with ulceration in how often these complaints were experienced.

A significantly higher proportion of medicated patients reported that abdominal complaints had some negative impact on their working capacity compared with surgically treated patients and controls ($P = 0·002$ and $P < 0·0001$ respectively) (*Table 4*). The proportion of electively vagotomized patients reporting complaints with significant impact on working capacity was greater than that in controls ($P = 0·005$). There was no difference between controls and patients having emergency PGV in the reported influence of abdominal complaints on working capacity ($P = 0·65$).

Patients who had medical treatment reported the use of antacids, H_2-receptor antagonists and proton pump inhibitors more frequently than vagotomized patients ($P < 0·0001$). Those who had emergency or elective PGV did not use these drugs significantly more than community controls ($P = 0·66$ and $P = 0·09$ respectively) (*Table 5*).

Discussion

Comparison of dyspeptic and abdominal complaints or symptoms among surgically and medically treated patients with peptic ulceration who have not had *H. pylori* eradication therapy is apparently of only historical interest. However, when incorporating community controls without known peptic ulceration, this comparison raises some questions that are also pertinent for the evaluation of other peptic ulcer treatment regimens. It illustrates the importance of relating clinical outcome in the evaluation of different treatment modalities to the prevalence of similar complaints in the population, and is also important when assessing which dyspeptic symptoms can be ascribed to peptic ulcer disease.

The most substantial finding in this study was the lack of difference in reported abdominal and dyspeptic complaints between vagotomized patients and healthy control subjects, and that surgically treated patients had fewer of such complaints than medically treated counterparts in this long-term follow-up.

It is commonly assumed that groups of surgically or medically treated patients with peptic ulcers represent a different spectrum of the disease and therefore should not be compared. On the other hand, comparison of different treatment regimens for the same disease might give valuable information, especially when, as in this case, a healthy population was incorporated. In this study, all patients with peptic ulceration treated medically were living in Tromsø and were treated according to the treatment regimens of Tromsø University Hospital. Medical therapy for peptic ulcers was standardized and H_2 blockers could be prescribed only by specialists on the first occasion. During relapses, patients might have been offered different regimens, but regardless of differences they represent the average clinical outcome of medically treated patients for that period. Similarly, vagotomized patients may have differences in the completeness of the PGV operation, but the group represents the average clinical outcome of the surgical treatment offered for peptic ulcer disease. Comparison of the two treatment strategies should therefore be of major clinical interest.

Among healthy community controls, responders might be more likely to be subjects with abdominal complaints. This selection bias could also be true for patients with peptic ulceration. However, nothing is known about the non-responders in this study regarding dyspeptic symptoms, although the prevalence of reported complaints in responders corresponds well to that in other population-based studies in the region[10,15–17].

With abdominal complaints, it is of major importance that qualitatively similar complaints are being compared. The frequencies of reported complaints and influence on working capacity (*Tables 3* and *4*) indicate that the complaints were comparable in all four populations regarding these qualitative aspects.

In this study the definition of dyspepsia used was that recommended by an international working group[12], which distinguished it from abdominal complaints because of its high prevalence and the heterogeneous nature of abdominal symptoms. Dyspeptic symptoms with this definition are still non-specific with respect to any underlying organic disease. The probability that dyspeptic complaints in patients with previously diagnosed peptic ulceration would represent organic disease is higher than in dyspeptic controls. Comparison of dyspeptic complaints between the three ulcer populations and controls must therefore be made with caution and with such reservation in mind.

With regard to abdominal and dyspeptic complaints, Muller *et al*[9]. found an almost identical Visick grade pattern, except for grade IV, 5 years after operation in patients having PGV and blood donors serving as healthy controls. When comparing abdominal and dyspeptic complaints, the present results confirm these similarities after more than 10 years of follow-up.

Of medically treated patients 25·4 per cent reported no abdominal or dyspeptic complaints. This is in agreement with Petersen *et al.*[8], who found that 28 per cent of medically treated patients had no complaints after the initial ulcer treatment with a similar follow-up time to that in the present study. The difference in length of follow-up between medically and surgically treated patients was minimal in this study and cannot explain the reported differences in abdominal and dyspeptic complaints.

A significantly higher proportion of patients who had medical treatment found that abdominal complaints had a negative impact on quality of life compared with vagotomized patients and controls. In another study 56 per cent of patients not undergoing operation claimed that abdominal symptoms had a negative impact on some aspects of life[8]. This is in accordance with the results of the present study (47·5 per cent, data not shown), and indicates that intermittent medical treatment with antisecretory drugs had insufficient effect on the symptomatic course of peptic ulcer disease. This is also supported by the significantly higher proportion of medical patients reporting reduced working capacity due to abdominal complaints compared with both surgically treated patients and controls.

The ulcer recurrence rate, based on information from the medical records of all patients having elective PGV at Tromsø University Hospital, was 8·7 per cent with follow-up of 1–17 years after operation[18]. Reported ulcer recurrence rates after surgical treatment for peptic ulceration vary in the literature, from below 10 per cent to over 40 per cent, depending on factors such as the surgeon's experience, type of vagotomy, site of the ulcer, length of follow-up, symptomatic or total recurrences, or time intervals of endoscopic investigations[3–6,19–26].

Antisecretory medication does not eradicate *H. pylori* infection and patients with ulcers who receive medical therapy therefore have an increased risk of ulcer recurrence and dyspeptic symptoms. Nor does vagotomy eradicate *H. pylori* from the gastric mucosa[27,28]. However, the reduced acid output and/or gastric sensory denervation following vagotomy does to some extent prevent symptomatic ulcer recurrence and reduce abdominal complaints better than medical suppression therapy alone[3,4].

The self-reported ulcer recurrence rate among medically treated patients in the present study is low compared with that in other reports[8,29–31]. Again, the recurrence rate in retrospective studies is biased by such factors as negative and false-positive reporting, maintenance treatment, frequency of endoscopic examinations, systematic control regimens or symptomatic recurrences, or length of follow-up.

In the few prospective randomized studies that compare PGV and medical treatment (cimetidine maintenance therapy) of duodenal ulcers, a significantly lower recurrence rate occurred in surgically treated patients[3,4,6]. The self-assessed ulcer recurrence rates in this questionnaire study are in accordance with these previous reports.

In conclusion, this questionnaire survey revealed that abdominal and dyspeptic complaints are common in the community population. The prevalence of such complaints was similar in patients with peptic ulcers who had had vagotomy and in community controls. The study also showed that surgically treated patients reported fewer abdominal and dyspeptic complaints than did patients with ulcer who received medical treatment only.

Even though minimally invasive techniques have been developed for PGV[32], the final requiem has been held for vagotomy as elective treatment for peptic ulceration[33]. However, those who would like to make patients with peptic ulcer disease healthier or freer from gastrointestinal symptoms than the community population will probably be disappointed. This is particularly important to consider when eradication of *H. pylori* might cure the disease and thereby ulcer recurrence, but will not necessarily cure all abdominal or dyspeptic complaints among patients with peptic ulceration.

Acknowledgements

The authors thank Tor Øydvin for designing the layout of the questionnaires, Anne Grethe Dahl for skilful help in administering the lists of patients and Bente Mathisen for professional typing of the manuscript. This work was supported by grants from the Norwegian Medical Association's fund for quality improvement and the Tromsø University Hospital research fund.

Oral colonization is unlikely to play an important role in *Helicobacter pylori* infection

A. OSHOWO, M. TUNIO, D. GILLAM*, A. J. BOTHA, J. HOLTON†, P. BOULOS and M. HOBSLEY

Background This clinical and microbiological study investigated whether *Helicobacter pylori* colonizes the mouth *en route* to the pyloric antrum. It has been suggested that oral colonies are a source of reinfection after eradication of gastric infection.

Methods Some 208 patients attending for routine diagnostic endoscopy for dyspepsia were recruited. Before endoscopy, samples were collected of saliva, supragingival and infragingival plaque, and swabs were taken from the tongue, mouth and pharynx. At endoscopy, gastric antral biopsies were taken for the rapid urease test, culture and histological examination. Gastric and duodenal juice samples were aspirated. Restriction nuclease digestion with HaeIII was employed on all specimens from patients in whom there was evidence of the organism in the mouth.

Results *H. pylori* was observed in dental plaque in only 15 patients, all from the 116 who had evidence of the organism in the stomach. Restriction endonuclease digestion demonstrated that in 13 of the 15 patients the strains were identical in mouth and stomach.

Conclusion Oral colonization is a rare event, but does occur. Its rarity suggests that it is not an important factor in reinfection.

Helicobacter pylori is a Gram-negative, microaerophilic, curved, rod-shaped bacterium that colonizes human stomach. This colonization causes active chronic and acute gastritis[1,2], is strongly associated with chronic duodenal ulcer, and may be a risk factor for gastric cancer. Despite being one of the commonest infections in the world, the exact route of transmission is still unclear[3]. Some researchers have implicated the oral cavity[4–8] as a reservoir for systemic infection and perhaps a sanctuary where eradication therapy is ineffectual, thus leading to reinfection. Others have reported an absence of this organism from the mouth[9,10]. The aim of this study was to determine whether *H. pylori* colonizes the oral cavity and whether, if it does, the organism in the mouth is the same strain as that in the stomach.

Patients and methods

A total of 208 unselected dyspeptic patients referred for upper gastrointestinal endoscopy were recruited. Informed consent was obtained. The study was reviewed by the local ethics committee. Exclusion criteria included patients with a potential infection risk, a history of bleeding tendency, antibiotic therapy in the preceding 8 months and the requirement for antibiotic prophylaxis. Immediately before endoscopy, the following specimens were collected: saliva, both supragingival and subgingival plaque using a sterile periodontal curette with a gentle upward scrape against the surface of the tooth, and a swab of the tongue, mouth and pharynx. During endoscopy, specimens were collected by aspiration via a trap collector of gastric juice and (separately, in 50 subjects only) duodenal juice down to the second part of the duodenum. Three antral mucosal biopsy specimens were obtained with sterile forceps: one was used immediately for the rapid urease test, one was cultured, and the third was stored at −70°C for subsequent analysis by polymerase chain reaction (PCR) and possible restriction endonuclease digestion. Statistical analysis was by standard methods including the binomial sign test.

Specimen preparation

The dental plaque, saliva and oropharyngeal swab were vortexed in sterile solution, cultured and used for PCR. Gastric and duodenal juice specimens were initially centrifuged at high speed and the sediments tested by PCR. One gastric antral biopsy was homogenized before culture and PCR. All specimens were cultured using Colombia agar with 5 per cent horse blood and amphotericin B 10 μg/ml. *H. pylori* was identified by growth condition, typical morphology in Gram-stained preparations, a positive oxidase and a positive urease reaction.

Extraction of genomic DNA from all clinical isolates was carried out with Puregene DNA isolation kits (Gentra Systems, Minneapolis, Minnesota, USA) and applied according to the manufacturer's instructions. Two 20-base oligonucleotide primers (Oswell DNA Service, Southampton, UK) designated HP1 (5′-CTG GAG AGA CTA AGC CCT CC-3′) and HP2 (5′-ATT ACT GAC GCT GAT TGT GC-3′) were used. The primers target areas of the 16*S* ribosomal RNA gene in which there is the least sequence homology, and amplify a 109-base pair product.

PCR was performed in a 100-ml mixture containing 10 ml PCR buffer (Tris–hydrochloric acid 10 mmol/l, pH 8·3, potassium chloride 50 mmol/l), 16 μl 2′-deoxynucleotide 5′-triphosphate 200 mmol/l, 1 μl AmpErase uracil *N*-glycosylase (Perlan Elmer, Branchburg, New Jersey, USA), 1 μl AmpliTaq DNA polymerase (Amersham International, Amersham, UK), 8 μl magnesium chloride 2·0 mmol/l, 10 μl HP1 and HP2 2 mmol/l,

Paper accepted 18 November 1997

and 5 μl DNA template. The mixture was made up to 100 μl by adding ultrapure water. This was then topped up with 50 μl sterile mineral oil to prevent evaporation during temperature cycling.

PCR reaction cycle

A two-step cycle was used in the automated thermocycler (Hybaid, Ashford, UK). This consisted of 40 cycles at 95°C for 30 s, 60°C for 30 s and 72°C for 30 s. The final cycle was maintained at 72°C for 5 min.

The amplified PCR products were analysed in ethidium bromide-stained agarose gel run at 8·8 V/cm for 30 min. The gel was photographed under ultraviolet light.

Restriction endonuclease

PCR products from patients in whom *H. pylori* had been detected in the mouth were digested with HaeIII (Sigma Diagnostics, Poole, UK). This was run in a water bath at 37°C for 4 h and electrophoresed in a 2 per cent agarose gel at 8·8 V/cm for 1 h.

Results

Using the criterion of culture and/or rapid urease test of the antral biopsies, 82 patients (39 per cent) were *H. pylori* positive and 115 were *H. pylori* negative (data were not available for the remaining 11 subjects). Using the criterion of PCR, the corresponding results were 116 positive and 92 negative.

No sample of gastric or duodenal juice was positive by culture or urease test. However, 36 samples (17 per cent) of gastric juice and six of 50 (12 per cent) samples of duodenal juice were positive by PCR.

With regard to the mouth, no salivary or swab sample was positive for *H. pylori* by any test. Two of 180 specimens of dental plaque were *H. pylori* positive by culture, and these two samples plus 13 more were positive by PCR. All of these 15 patients were also positive for *H. pylori* in both antral biopsy and gastric juice. Restriction endonuclease digestion of the amplified PCR product from these 15 patients showed that 13 of the dental plaque isolates had identical restriction digest patterns to those of the organisms in the stomach, whereas in the other two patients the patterns were slightly different. On the other hand, only four of the 15 patients had a similar pattern in all three sites (plaque, stomach and duodenum); in the other 11 the duodenal organisms were definitely different.

Discussion

The PCR technique seemed to be more sensitive than culture or the rapid urease test in detecting *H. pylori*[11]. The significance of this finding, which has been well reported, is not clear. It may mean, as some believe, that culture and the urease test occasionally fail to demonstrate live organisms that are present in very low numbers. However, the fact that PCR sometimes finds evidence of *H. pylori* in gastric, and even in duodenal, juice (the organism is particularly sensitive to extremes of pH[12]) suggests that the molecular technique might be demonstrating fragments of the dead organism that still contain intact the targets of the primers.

In the oral samples there was never any evidence of *H. pylori* except in plaque. In 15 of 208 plaque samples PCR was positive for the organism, but in only two of these was the PCR result accompanied by a positive culture. It is concluded that colonization of the mouth by *H. pylori* is a rather unusual event and that it does not occur except in plaque. Depending on the view taken of the relationship between PCR results and those from culture and the rapid urease test, it may also be concluded, either that the greater sensitivity of PCR is responsible for the larger score by that technique, or that the culture gives the true picture of present colonization whereas the PCR is evidence of (recent) past colonization. At present, it is not possible to choose between these interpretations.

Whatever interpretation of the oral findings is chosen, the fact remains that, of 116 patients with evidence from PCR of *H. pylori* in the stomach, 15 were also positive in the mouth; by contrast, of 92 patients with no trace of the organism in the stomach, none showed evidence of *H. pylori* in the mouth. This asymmetrical distribution of the 15 patients is highly significant ($P < 0.0002$, binomial sign test). In other words, colonization in the mouth is linked with colonization in the stomach. This finding is further supported by the restriction endonuclease digestion studies.

As already noted, some observers have reported that they could not find *H. pylori* in the mouth, whereas others have confirmed its presence. Possible reasons for these discrepancies include the small numbers of patients studied, differences in population prevalence, and the difficulty of culturing this fastidious micro-organism from the oral cavity with its complex and varied normal flora. Even in the present study, positive cultures were obtained from plaque in only two of the 116 subjects who were PCR positive in the stomach. Clearly this small number is not significantly different from the zero score in the plaque in the 92 PCR-negative subjects. However, the present study provides the largest number of data of all published papers on the detection of *H. pylori* in the oral cavity, and the use of PCR and restriction endonuclease digestion was crucial in establishing the link between mouth and stomach.

It is concluded that *H. pylori* sometimes colonizes dental plaque, but it would appear that such colonization is transient. The hypothesis that the mouth is a sanctuary in which the organism can survive the attack of antibiotics and later produce reinfection gains little support from these data.

Surgical Infection Society of Europe Abstracts

The following abstracts and posters were presented at the 11th annual meeting of the Surgical Infection Society of Europe held in London on 15–16 May 1998.

Abstracts of papers

Endotoxin tolerance induces enhancement of phagocytic activity of mononuclear cells in a porcine endotoxin shock model

K. H. Staubach, L. Song, H. Weber, M. Sabransky and H. P. Bruch, *Department of Surgery, Medical University of Lubeck, Lubeck, Germany*

Background Endotoxin (ET) tolerance represents a non-specific refractoriness to ET as an essential protective mechanism in the early phase of infection to prevent unreasonable expansion of the inflammatory immune response. Its exact biological basis remains unclear, besides a well known downregulation of pro-inflammatory mediators in endotoxaemia. The aim of the present study was a quantitative *in vitro* evaluation of mononuclear phagocytic activity in ET shock.

Methods Seven pigs were immunized over 5 days by increasing doses of atoxic ET from *Rhodopseudomonas sphaeroides* (group T) and compared with six control animals (group C) before induction of an ET shock with a continuous ET challenge of *Salmonella friedenau* at 250 ng kg^{-1} h^{-1}. Phagocytosis was measured by flow cytometry, demonstrating ingestion of opsonized fluorescent *Escherichia coli*. A commercial test kit (Phagotest; Orpegen, Heidelberg, Germany) was used for the tests.

Results

	Immunization period (days)					ET shock (h)				
	1	2	3	4	5	1	3	6	9	12
C	679	715	631	670	—	459	723	554	210	—
T	532	639	529	438	—	294	683	617	743	703

Values are fluorescence intensity units

Conclusion The functional assessment of mononuclear cells of ET-tolerant animals revealed an increase in phagocytic activity compared with control animals which resulted in a significantly higher survival rate ($P = 0·05$).

Heparin and enoxaparin enhance endotoxin-induced tumour necrosis factor α production in human monocytes

M. Heinzelmann, M. Miller, L. E. Gordon and H. C. Polk Jr, *Price Institute of Surgical Research, University of Louisville, Louisville, Kentucky, USA*

Background The ability of heparin to bind antithrombin III and to inhibit the coagulation cascade is widely used in clinical practice. Heparin has other potentially important properties, such as binding to various proteins (e.g. fibronectin, heparin binding protein or chemokines) or to leucocyte receptors (e.g. selectins) and could be used as a pleiotropic immunomodulator. It was hypothesized that heparin and enoxaparin (low molecular weight heparin) would alter the effect of another potent immunomodulator, endotoxin (lipopolysaccharide; LPS), which induces release of tumour necrosis factor (TNF) α from monocytes.

Methods Monocytes from five healthy donors were isolated by density gradient centrifugation and stimulated for 24 h with heparin 0·1–1000 μg ml^{-1}, enoxaparin 0·1–1000 μg ml^{-1} and LPS 10 ng ml^{-1}. Monoclonal anti-CD14 antibody (MY4 10 μg ml^{-1} or isotype-matched immunoglobulin G control was used to assess the role of CD14 blockade. TNF-α release was measured by enzyme-linked immunosorbent assay.

Results Initial dose–response studies demonstrated that heparin at more than 10 μg ml^{-1} and enoxaparin 1000 μg ml^{-1} significantly increased LPS-induced TNF-α release. Subsequent blocking studies confirmed that heparin is more potent than enoxaparin in enhancing LPS-induced TNF-α release. Blockade of CD14 inhibited the effect of LPS as well as the effect of heparin and enoxaparin in enhancing LPS-induced TNF-α release.

Conclusion Heparin and enoxaparin enhance LPS-induced TNF-α release from isolated monocytes. This immunomodulatory effect is stronger for heparin than for enoxaparin and may be biologically important in patients with sepsis with increased LPS levels. Binding of LPS to CD14 on monocytes is the important initial mechanism to induce TNF-α release from monocytes, because blockade of CD14 inhibited both the effect of LPS and the enhancing effect of heparin and enoxaparin.

Postoperative wound infection rate after hernia repair: a European study

M. Cainzos, F. Lozano, I. Pulay, T. Hau, L. Dominioni and I. Sayek, *Hospital General de Galicia, Santiago de Compostela, Spain*

Background This was a prospective controlled study of wound infection after hernia repair in five European countries: Spain, Hungary, Germany, Italy and Turkey.

Methods The period of the study was from 1 February to 30 April 1996 and included patients aged 18 years or more. The study determined wound infection rates in all abdominal wall and incisional hernia repair surgery and established the value of antibiotic prophylaxis in cases of hernia repair with a mesh. In these cases, cephazolin, in a single 1-g dose, was administered during induction of anaesthesia. For analysis the computer program 'Surgery' was used. Some 229 surgical patients were included of mean age 55·9 years; 76·9 per cent were male and 23·1 per cent female. In all, 213 patients were submitted to elective surgery and 16 to emergency operation. There were three epigastric hernias, 16 umbilical, seven femoral, 159 inguinal, 40 incisional and four others.

Results Sixteen (7·0 per cent) patients developed postoperative wound infections: ten superficial and six deep. Fifteen (6·9 per cent) of the 216 patients submitted to clean surgery developed wound infections, and one of 11 who had clean-contaminated surgery. There were no statistical differences between staff surgeons and residents. In 107 patients the duration of operation was less than 1 h and the rate of wound infection was 5·6 per cent; in 93, the duration was between 1 and 2 h and the infection rate was 7·5 per cent; and in 24 the duration was over 2 h and three patients developed a wound infection. The greatest rate of wound infection occurred in umbilical hernias (two of 16); the rate was 6·9 per cent for inguinal and two of 40 for incisional hernia repair. In 20 patients a mesh was placed and antibiotic prophylaxis was used; one of these 20 patients developed a wound infection compared with 7·2 per cent of 209 patients in whom hernia repair was done without a mesh. Thirty patients received antibiotic prophylaxis, of whom two developed wound infections; of the 199 patients who did not receive antibiotic prophylaxis 14 (7·0 per cent) developed wound infections. The mean duration of the postoperative period was 5·3 days in patients without wound infection and 6·3 days in patients with infections; there were no deaths.

Prospective randomized double-blind clinical study of perioperative immunonutrition

L. Gianotti, M. Braga, A. Vignali, G. Radaelli, G. Mari and V. di Carlo, *Department of Surgery, University of Milan, Milan, Italy*

Background It has been shown that perioperative immunonutrition upregulates the immune response, improves gut oxygen metabolism and modulates the inflammatory response after surgery. This trial evaluated the use of perioperative immunonutrition to improve outcome after major abdominal operations.
Methods Some 206 patients with gastric, pancreatic or colorectal cancer were randomized in a double-blind fashion to receive either a formula enriched with arginine, ω-3 fatty acids and RNA (group E; $n = 102$) or a control isonitrogenous, isocaloric, enteral diet (group C; $n = 104$). Seven days before surgery the patients drank 1 litre per day of either the control or enriched diet. Postoperative jejunal infusion with the same diet began 6 h after surgery and continued for 7 days after operation. Twenty patients were withdrawn from the study; six were not compliant with the preoperative diet and 14 underwent palliative surgery for intraoperative evidence of metastatic disease.
Results The two groups were comparable for preoperative, age, sex, weight, Karnofsky index, nutritional parameters, haemoglobin, type and duration of surgery, blood loss and rate of transfusion. Fifteen of the 186 patients who underwent curative surgery had an anastomotic dehiscence (five in the enriched group, ten in the control group). Some 171 patients were valid for evaluation (85 in group E and 86 in group C). There were no deaths in group E and one patient died in group C (P not significant). The rate of postoperative infection was 11 per cent (nine of 85 patients) in group E and 26 per cent (22 of 86) in group C ($P = 0·004$). Mean(s.d.) duration of antibiotic therapy was 6·7(1·2) days in group E and 9·1(2·5) days in group C ($P = 0·001$). Length of hospital stay was 11·1(4·4) days in group E and 12·9(4·6) days in group C ($P = 0·01$).
Conclusion Perioperative immunonutrition improved outcome in patients with cancer undergoing major surgery.

The battle against methicillin-resistant *Staphylococcus aureus*: 'search and destroy' can work in a high-prevalence region

H. van Goor, E. J. van Nieuwenhoven and A. Voss, *Departments of Surgery and Medical Microbiology, University Hospital Nijmegen, Nijmegen, The Netherlands*

Background In the Netherlands, the proportion of methicillin-resistant *Staphylococcus aureus* (MRSA) among *S. aureus* isolates is low (1·5 per cent) despite an increase in neighbouring countries during the past decade. Since 1989 a nationwide guideline has been followed, which is based on the principles of 'search and destroy'. The mainstay of this guideline is that patients who potentially carry MRSA, predominantly those who are transferred from foreign countries, are strictly isolated in a single room with hospital staff wearing a mask, cap, gown and gloves. Screening cultures are taken from the nose, throat, perineum, skin lesions and wounds (sputum if present and urine in the event of a catheter) of these patients, and interventions such as surgery are postponed, whenever possible, until the results of cultures are known. This guideline is criticized because of its failure rate and high costs.
Methods From a 5-year retrospective survey this guideline has been evaluated.
Results Between January 1992 and September 1997, 1803 samples were taken from 363 patients for screening of MRSA. In 355 patients, who appeared to be MRSA negative, a total of 1459 cultures was taken, mean 4 (range 4–76) cultures, whereas in eight patients who appeared to be MRSA positive a total of 344 cultures was taken, mean 43 (range 4–169) cultures. Some 165 (45 per cent) were surgical patients; 25 per cent of the patients were treated in the outpatient clinic. The eight MRSA-positive patients (trauma four, respiratory insufficiency two, cerebral haemorrhage one, urological disorder one) had to be treated clinically with vancomycin. All of these patients were transferred from a hospital in a foreign country and fulfilled the criteria for MRSA screening according to the guideline. In this 5-year period, no culture from other hospital patients revealed MRSA. The cost for MRSA-negative patients was $36 000. The costs of cultures, preventive measures and antibiotic treatment in the eight MRSA-positive patients were more than twice as high.
Conclusion The prevalence of MRSA in a Dutch university hospital is low. A nationwide guideline of 'search and destroy' in a European region of high MRSA prevalence is highly effective and seems to be cost saving. Screening programmes for MRSA would benefit from identification of so-called MRSA-free hospitals.

Sex and genetics as new determinants in sepsis

J. Schroder, V. Kahlke, K. H. Staubach, P. Zabel and F. Stuber, *Departments of Surgery, Universities of Kiel and Lubeck, and Department of Anaesthesiology, University of Bonn, Bonn, Germany*

Background The prognosis of sepsis has been found to be genetically determined, with a high mortality rate in patients who are homozygous for the tumour necrosis factor (TNF) B2 allele. In animal studies sex differences relate to hormonal and immunological changes which are associated with an increased susceptibility to sepsis in males.
Methods The prognostic value of sex and genetic determination was evaluated in 51 patients (19 women) with surgical sepsis. In a subgroup of patients ($n = 18$) TNF gene polymorphism was determined in relation to sex. There were no differences between the men and women with respect to age (mean age 56 years for women, 53 years for men), and cause and severity of sepsis. The predominant causes of sepsis were peritonitis and necrotizing pancreatitis.
Results The prognosis of sepsis was significantly different in women compared with men. Twenty-four of 33 men and five of 19 women died in hospital ($P < 0·01$, log rank test). Some 40 per cent of patients who were homozygous for the *TNFB2* allele died while one-third of patients who were heterozygous (*TNFB1/TNFB2*) survived. Of 12 men in whom genomic polymorphism was studied, seven died. Six of these non-survivors were homozygous for the *TNFB2* allele. Both female patients who died were homozygous as well.
Conclusion Sex differences could be confirmed in human sepsis with a significantly improved prognosis for women. Genetic determination in female and male patients homozygous for *TNFB2* was associated with poor prognosis. Because of their prognostic importance, sex and genetic screening should be regarded as important determinants in further sepsis studies.

Intestinal intramucosal pH is the pivotal indicator of mucosal damage in goal-directed therapy of endotoxin shock

T. Sautner, M. Riegler, P. Gotzinger and R. Fugger, *Department of General Surgery, University of Vienna, Vienna, Austria*

Background 'Goal-directed' therapy of patients with septic shock has been frequently advocated to avoid end-organ damage and has been focused at haemodynamic parameters and variables of oxygen transport. More recently intramucosal pH (pH_i) obtained by tonometry has been introduced but its value as an indicator of mucosal integrity in septic shock is uncertain.
Methods Nineteen pigs were infused with $250\,\mu g\,kg^{-1}$ *Escherichia coli* endotoxin over 30 min and thereafter subjected to fluid resuscitation to maintain postcapillary wedge pressure at pre-endotoxin levels. Four animals received fluid only while three groups of five animals each underwent additional catecholamine therapy either to maintain mean arterial pressure (MAP) above 70 mmHg by individual doses of adrenaline (group

E) or noradrenaline (group NE) or to increase cardiac output (CO) by a constant infusion of dopexamine 7 µg kg^{-1} (group DX). After induction of anaesthesia, catheters were introduced into the carotid artery and jugular vein for haemodynamic measurements, and drug and fluid delivery. CO was obtained using a thermodilution artery and the portal vein, and a catheter was inserted into the portal vein. The pH$_i$ was obtained by a tonometer balloon in the sigmoid. Animals underwent therapy for 4 h. At the end of the experiment specimens of ileal and colonic mucosa were taken, processed and subjected to morphometry after haematoxylin and eosin staining. Damage to the mucosa was defined as disruption of the epithelial layer and was documented as a percentage of the investigated surface.

Results Therapy led to a maintenance of MAP above 70 mmHg at 4 h in groups E and NE. CO was significantly increased to a mean(s.d.) of 137(7) per cent in groups E, NE and DX at 4 h. pH$_i$ was decreased in all groups by 3·5–9·4 per cent. Mean mucosal damage ranged from 4 to 46 per cent depending on the group. Regression analysis of the impact of the variables MAP, CO, arterial oxygen content, mixed venous saturation and pH$_i$ at 4 h on percentage of ileal mucosal damage showed significance only for pH$_i$ ($r = -1{\cdot}1$, $P = 0{\cdot}01$). When the relative drop of pH$_i$ from baseline to 4 h was introduced as a variable, significance was established also for damage to the colonic mucosa ($r = 0{\cdot}67$, $P < 0{\cdot}05$).

Conclusion pH$_i$ is the pivotal independent indicator of damage regarding disruption of the intestinal mucosa and potential sequelae in endotoxin-induced shock. Therefore maintenance or improvement of pH$_i$ should be given priority over other therapeutic goals.

Production of interleukin 6 and monocyte chemoattractant protein by the human peritoneum during abdominal surgery *in vivo* and *in vitro*

J. Riese, C. Denzel, M. Zowe, W. Hohenberger and W. Haupt, *Department of Surgery, University Erlangen-Nuremberg, Germany*

Background Major abdominal operations as well as peritonitis lead to an increase of various cytokine concentrations in plasma. The peritoneum is a potential source of cytokines. The production of interleukin (IL) 6 and monocyte chemoattractant protein (MCP) 1 by the peritoneum *in vivo* during elective major abdominal operations was investigated. In addition the reaction of the peritoneum to bacteria or lipopolysaccharide (LPS) was tested *in vitro*.

Methods A small chamber (inner volume 500 µl) was fastened to the patient's parietal peritoneum, covering an area of 3·1 cm^2. During the operation (at least 5 h), the chamber was perfused with buffered electrolyte solution (2 ml h^{-1}) and the perfusate was collected hourly. For *in vitro* culture, a small piece (10 cm^2) of the peritoneum was excised, placed across the wells of a microtitre plate, fixed by means of the plate cover and subsequently incubated with culture medium containing LPS or whole bacteria (*Escherichia coli*) for 5 h. The culture supernatants and perfusate samples were assayed for IL-6 and MCP-1 concentrations by enzyme-linked immunosorbent assay.

Results Production of IL-6 and MCP-1 started within the first hour. IL-6 was released thereafter constantly (mean(s.d.) 90(50) pg cm^{-2} h^{-1}) during the whole of the procedure. MCP-1 secretion increased from 66(26) pg cm^{-2} during the second hour to 237(199) pg cm^{-2} during the fifth hour. Peritoneum cultured with LPS or bacteria released amounts of IL-6 and MCP-1 that were significantly higher (6175(3515) and 3758(2457) pg cm^{-2} h^{-1}) than those of the corresponding control samples.

Conclusion The peritoneum reacts to surgical procedures with production of IL-6 and MCP-1. These are mediators that participate in the initiation of an inflammatory process. Moreover, it is able to upregulate its mediator production in the presence of Gram-negative bacteria or LPS. Modulation of the cytokine production of the peritoneum may offer treatment options for inflammatory processes in the abdomen.

Nitric oxide production mediates cytokine-induced inhibition of hepatocyte gluconeogenesis and protein synthesis

J. Arias-Dias, A. del Real, N. Villa, C. Garcia-Carreras, J. Calatayud, E. Vara and J. L. Balibrea, *Department of Biochemistry, School of Medicine, and Department of Surgery, Hospital San Carlos, Madrid, Spain*

Background Cytokines are thought to play an important role in the hepatocellular dysfunction that occurs during sepsis, and they have been implicated in the regulation of the nutritional state. The signal transduction mechanisms by which cytokines exert their effects have not been elucidated fully. Several studies have shown that nitric oxide is produced in large amounts *in vitro* by hepatocytes following exposure to septic stimuli. The aim of this study was to investigate a possible mediation by nitric oxide and guanosine 3′,5′-cyclic monophosphate (cGMP) of the effect of cytokines on gluconeogenesis and protein synthesis by isolated rat hepatocytes.

Methods Cells were isolated by the collagenase perfusion method and cultured for 24 h before making the following additions: tumour necrosis factor (TNF) α, interleukin (IL) 1, the nitric oxide donor morpholinosydnonimine (SIN-1), *N*-nitro-L-arginine (NAME), aminoguanidine (AG), 8-bromo-cGMP, methylene blue and combinations thereof. After that, cells were cultured for another 60 min or 24 h. Protein synthesis was determined as the incorporation of [^{14}C]leucine in proteins, and gluconeogenesis as the glucose production from [^{14}C]alanine.

Results Both TNF-α and IL-1 decreased the [^{14}C]leucine incorporation into proteins (mean(s.d.) 1·60(0·12) and 1·00(0·09) *versus* 2·95(0·13) nmol per 10^5 cells per 60 min for TNF-α and IL-1 respectively *versus* controls; $n = 11$, $P < 0{\cdot}01$) and the synthesis of glucose (10·81(0·94) and 10·87(1·44) *versus* 14·50(1·50) nmol per 10^5 cells per 24 h; $n = 11$, $P < 0{\cdot}05$), which were also diminished by SIN-1 (0·79(0·09) *versus* 2·95(0·13) nmol per 10^5 cells per 60 min and 8·46(1·30) *versus* 14·50(1·50) nmol per 10^5 cells per 24 h respectively; $n = 11$, both $P < 0{\cdot}01$). The cytokine effect was accompanied by an increase in nitric oxide synthesis (199·1(6·9) and 214·7(9·2) *versus* 134·4(7·4) pmol per 10^5 cells per 24 h for TNF-α and IL-1 respectively *versus* controls; $n = 11$, both $P < 0{\cdot}01$) and cGMP (0·95(0·14) and 0·96(0·11) *versus* 0·56(0·04) pmol per 10^5 cells per 24 h; $n = 11$, $P < 0{\cdot}01$) and lipid hydroperoxide (1·97(0·14) and 2·02(0·15) *versus* 1·12(0·07) nmol per 10^5 cells per 24 h; $n = 11$, $P < 0{\cdot}01$) cell content. Both NAME and AG were able to reverse all these effects.

Conclusion The generation of nitric oxide may mediate the inhibition of protein synthesis and gluconeogenesis caused by cytokines in rat hepatocytes.

The surgeon's impact on the abdominal compartment in abdominal sepsis

A. Billing, H. Winter, W. Steines, M. Jochum and F. W. Schildberg, *Department of Surgery, LMU Munich, Klinikum Grosshadern, Munich, Germany*

Background Rapid and efficient surgical management of abdominal sepsis is known to be critical for outcome in peritonitis. Little, however, is known about the impact of surgery on the pathophysiological environment in the abdominal cavity or whether cytokines can be washed out.

Methods In 19 patients with diffuse peritonitis intra-abdominal cytokines (interleukin (IL) 6 and IL-8), phagocyte lysosomal enzymes (elastase, cathepsin B, myeloperoxidase) and functional enzymes (opsonins, antithrombin III (AT-III)) were followed during and after operation (48 h). A second group of 13 patients underwent staged laparotomy. In these patients the same variables were examined and compared.

Results Lysosomal enzymes as well as cytokine levels were raised about 1000-fold in the initial peritonitis exudates. Intra-abdominal lavage resulted in a profound but very short-lasting reduction of these parameters. By 2 h later, concentrations were back to almost the original values and then decreased slowly over 2 days,

but only when surgery was successful. The same pattern was found in purulent exudates drawn in etappenlavage operations. The levels of the above variables stayed high until obvious clearance of the abdominal cavity was obtained. The concentration of opsonins and AT-III in peritoneal exudates was about 60 per cent that of patients' sera but in purulent exudates a distinct deficit in protein function was found. Only in clear exudates did protein activity match the protein concentration.
Conclusion Surgery in peritonitis resulted in a very short-lasting washout of mediators of inflammation followed by a profound relapse. A slow decrease of these parameters could be observed after 48 h if the source of the peritonitis had been eradicated. It is concluded that the main benefit of staged laparotomy is the supervision of source control rather than the effect of lavage.

Translocation of bacteria and endotoxin to mesenteric lymph nodes and the inflammatory consequences

U. Schoffel, R. Amberg, R. Harling, R. Schandel, K. Pelz v. Specht and E. Farthmann, *Departments of Surgery, Bacteriology and Legal Medicine, University of Freiburg, Freiburg, Germany*

Background Translocation of intestinal bacteria to mesenteric lymph nodes (MLNs) has been documented in humans in a variety of circumstances, yet its clinical significance remains to be established. Depending on the underlying disease, reported translocation rates range between 0 and 70 per cent. To correlate translocation with local and systemic responses, the translocation of bacteria and endotoxin to MLNs, the inflammatory response within the MLNs and respective systemic effects were investigated in a series of patients with carcinoma of the caecal region.
Methods Two lymph nodes were removed from the right colonic mesentery of each patient before resection. The presence of bacteria in the lymphatic tissue was determined by either bacteriological culture methods or DNA preparation (polymerase chain reaction (PCR)). Determination of local and systemic inflammatory responses was performed by analysis of inflammatory mediators in plasma and MLN supernatants, and by immunohistochemistry.
Results Living bacteria (mostly staphylococci) were detected by culture methods in seven of the ten patients and in nine of 20 lymph nodes. PCR revealed traces of Enterobacteriaceae in four of ten patients and in six of 20 MLNs. There was no detectable bacteraemia. Endotoxin (more than 0·1 pg ml^{-1}) was found in the plasma of seven patients (median 0·65 pg ml^{-1}) and in nine MLNs (median 7 pg per 25 mg) of five patients. Only in four patients was endotoxin detected simultaneously in MLNs and plasma. Gram-negative MLN cultures correlated with endotoxin concentrations in MLN homogenates. However, bacteriological data and endotoxin concentrations did not correspond to local or systemic concentrations of inflammatory mediators (tumour necrosis factor α, interleukin (IL) 6, IL-8, IL-10, CD14).
Conclusion From these results it may be concluded that translocation of bacteria and endotoxin to the MLN level occurs in a large majority of patients with caecal carcinoma. This, however, may be without clinical significance since detectable inflammatory reactions did not correspond to the degree of translocation, neither at the local nor at the systemic level. Additionally, there may be considerable variations in inflammatory reactions and the extent of contamination by bacteria and endotoxin between different lymph nodes from a single patient.

Control of the use of prophylactic antibiotics in surgery in Belgium

J. P. Sion, M. Bossens and H. Goossens, *University of Antwerp, Antwerp and INAMI/RIZIV, Brussels, Belgium*

Background The prophylactic use of antimicrobial agents in surgery is widespread practice. Different scientific organizations have published guidelines for the prophylactic use of antibiotics. Recently the degree of adherence to guidelines and real practice was studied in Belgium. In 11·4 per cent of the operations for which prophylaxis is indicated, it was not given. Prophylaxis was given in 55·6 per cent of the operations in which it was not indicated; 15 per cent of courses exceeded 2 days. To stimulate the use of guidelines and control the dispensing, a budget based on surgical intervention was introduced.
Methods A multidisciplinary group of experts, using leading guidelines, indicated for all surgical interventions the theoretical need for antimicrobials and the best choice of product(s). In Belgium, antimicrobials used in hospitals are reimbursable. Patient-based hospital listings, describing details of surgical interventions and drugs administered, must be sent to the paying insurance company. The price setting of reimbursable drugs is the responsibility of the Ministry of Economic Affairs. As a consequence, the price is fixed. Using the list compiled by the multidisciplinary group, administrators calculated, for each intervention, the amount of money necessary for appropriate prophylaxis.
Results It was decided to finance hospitals for the antimicrobial prophylaxis using a fixed budget linked to the surgical intervention. For registration reasons, it was decided to divide the total budget to a first fixed 75 per cent of the budget linked to the surgical fee and to a second part being 25 per cent of the reimbursable price of all antimicrobials given during a 3-day perioperative period.
Conclusion This strategy was introduced by law in Belgium in May 1997. Many local working groups discussed thoroughly the introduction of this new strategy. To optimize further the rules and the application, a national working group was set up. In many hospitals, guidelines on the prophylactic use of antimicrobial agents have been updated. In general, many hospital pharmacists observe an important reduction in prophylactic antimicrobial use. No data are available concerning the probable improvement in quality.

Prognostic peritonitis model: validation of a score based on control of an infective focus in patients with postoperative peritonitis

A. Rohrborn, C. Ohmann, O. Potreck and C. Ebener, *Department of General and Trauma Surgery, Heinrich Heine University, Dusseldorf, Germany*

Background Severe cases of peritonitis have a high associated mortality rate. In terms of decreasing resources there is an urgent need to identify patients at high risk for complications. None of the common scoring systems includes information on intraoperative control of the septic focus, although this is considered the most important single factor for outcome prediction. The peritonitis prediction model (PPM) identified patients at risk more accurately than other scores. The score was validated by applying it to a cohort of patients with postoperative peritonitis and at high risk for postoperative complications.
Methods From October 1994 to October 1997 patients with postoperative peritonitis were followed prospectively. Abscesses were included when open surgical drainage was necessary. Besides demographic data, details of underlying disease, concomitant disease, preoperative duration of symptoms, source of peritonitis, bacteriology, mode of repair, preoperative and postoperative organ failure, septic and non-septic complications, and circumstances of death were recorded. Score values were calculated from the data using the PPM method (Acute Physiology Score + 1/2 age + 3 × number of concurrent diseases + 25 (if infective focus unresolved) + 3 × Goris Multiple Organ Dysfunction score on postoperative day 1).
Results There were 55 patients with peritonitis, of whom 16 died. With the cut-off point of a score of less than 55 points, only one of 24 patients died in the low-risk group and 15 of 31 in the high-risk group. In contrast, when Acute Physiology And Chronic Health Evaluation (APACHE) II was used, with a cut-off point of below 10 points, three of 24 patients in the low-risk group died and 18 of 31 patients in the high-risk group survived. There was only one patient with an uncontrolled infective focus in the low-risk group as defined by PPM while there were eight of these in the low-risk group for APACHE II. In the low-risk group after

PPM there were 0·18 infectious complications per patient and in the high-risk group the mean was 1·1. In groups identified by APACHE score the values were 0·44 and 0·93.
Conclusion Postoperative peritonitis is one of the most lethal complications in abdominal surgery. The PPM is able reliably to identify patients at low risk for complications, thus focusing attention on a subgroup of patients with a 50 per cent risk of fatal outcome. Postoperative infectious complications are predicted as well for the high-risk group. The accuracy of PPM is superior to that of APACHE II.

Contribution of leptin to the metabolic response to sepsis

G. L. Carlson, M. Saeed, R. A. Little and M. H. Irving, *Department of Surgery and North Western Injury Research Centre, University of Manchester, Manchester, UK*

Background Leptin, a protein secreted by adipose tissue, has metabolic effects similar to sepsis, producing an increase in resting energy expenditure (REE) and anorexia. Since leptin secretion has been shown recently to be induced by endotoxin the authors have examined whether the metabolic effects of sepsis might be attributable to increased plasma leptin concentration.
Methods Twenty adult patients with abdominal sepsis (sepsis score 10–27, median 16) were studied within 96 h of admission and compared with 20 healthy control subjects. Fasting REE and plasma insulin, cortisol and leptin concentration were measured by indirect calorimetry and radioimmunoassay respectively. Fat mass (FM) was measured by anthropometry.
Results REE, FM and cortisol concentration were significantly greater in patients with sepsis than healthy controls but fasting plasma insulin and leptin concentrations were not.

	Control	Septic
REE (kcal kg FFM^{-1} day^{-1})	30·2(4·3)	36·0(7·2)*
FM (kg)	15·5(9·4)	23·4(4·2)*
Insulin (μunits ml^{-1})	6·6(2·9)	8·4(5·3)
Cortisol (μmol l^{-1})	250(151)	540(172)*
Leptin (ng ml^{-1})	7·0(5·2)	6·9(6·1)

Values are mean(s.d.). *$P < 0{\cdot}01$.

Leptin concentration correlated significantly with FM in controls ($r = 0{\cdot}78$, $P < 0{\cdot}001$) and patients with sepsis ($r = 0{\cdot}74$, $P < 0{\cdot}001$), but the slope of the line relating the variables was significantly lower in sepsis ($F = 1{\cdot}62$, $t = 2{\cdot}34$, $P < 0{\cdot}05$). Leptin concentration also correlated significantly with fasting plasma insulin concentration in controls ($r = 0{\cdot}67$, $P < 0{\cdot}001$) and patients with sepsis ($r = 0{\cdot}55$, $P < 0{\cdot}05$).
Conclusion Sepsis is not associated with increased plasma leptin concentration, either in absolute terms or relative to FM. Leptin is unlikely to play a primary role in the metabolic effects of human sepsis.

Cytokine production by human peritoneal mesothelial cells

P. Kinnaert, B. Bouronville and J. P. De Wilde, *Hôpital Erasme, Brussels, Belgium*

Background It has been demonstrated previously that monolayers of human peritoneal mesothelial cells (HPMCs) are able to release various cytokines after stimulation with heat-killed micro-organisms, suggesting that these cells play an active role in abdominal inflammatory reactions. In a normal setting, HPMCs are in contact or in close vicinity with other cell types (macrophages, fibroblasts, lymphocytes, other white blood cells) which also release inflammatory mediators when they are activated. This study determined the effect of these mediators on the response of HPMCs to heat-killed *Escherichia coli* and an attempt was made to modulate this reaction.
Methods Monolayers of confluent HPMCs were incubated with various compounds and stimulated with heat-killed *E. coli*. Some 24 h later, the concentration of interleukin (IL) 6, IL-8, RANTES and monocyte chemoattractant protein (MCP) 1 was measured in the supernatants by enzyme-linked immunosorbent assay.
Results

	Cytokine production			
	IL-6	IL-8	RANTES	MCP-1
TNF-α (0·1–1·0 ng ml^{-1})	↑a	↑a	↑s	↑a
IFN-α (1 × 10^3 units ml^{-1})	↑a	0	↑s	↑a
IFN-γ (1 × 10^3 units ml^{-1})	↑	0	↑s	↑a
IL-10 (500 ng ml^{-1})	0	0	0	0
Indomethacin (0·1–5 μg ml^{-1})	0	0	0	0
Zymosan (1 mg ml^{-1})	0	0	↓	0

TNF, tumour necrosis factor; IFN interferon. ↑, Increase; ↓, decrease; a, additive effect; s, synergistic effect; 0, no effect

Conclusion These data demonstrate that the production of cytokines by HPMCs stimulated by *E. coli* may be enhanced by some mediators secreted by cells present in the abdominal cavity. They suggest that prostaglandins secreted by HPMCs do not influence the output of IL-6, IL-8, RANTES and MCP-1. Zymosan, which has a protective effect in experimental peritonitis, selectively decreases RANTES secretion. Together with the experiments conducted with interferons, this result indicates that it is theoretically possible to alter the cellular composition of an intraperitoneal inflammatory reaction. Whether this is beneficial remains to be investigated.

Bi-allelic *NcoI* polymorphism within the tumour necrosis factor locus and its association with the prognosis and outcome of patients with sepsis

Th. Maseizik, B. Schluter, U. Mittelkotter, H. B. Reith and A. Thiede, *Department of Surgery, University of Wurzburg, Wurzburg, and Institute for Clinical Chemistry and Laboratory Medicine, University of Munster, Munster, Germany*

Background Tumour necrosis factor (TNF) α plays a central role in the pathophysiology of sepsis, septic shock and multiple organ failure. These host reactions are associated with increased TNF levels in the circulation, presumably due to increased TNF production.
Methods In a group of patients with sepsis, a bi-allelic *NcoI* TNF-β polymorphism was studied and correlated to TNF plasma level, TNF p55 receptor level, outcome and the incidence of multiple organ failure.
Results Patients homozygous for the allele *TNFB2* displayed higher multiple organ failure scores than heterozygous (*TNFB1*/*TNFB2*) patients.
Conclusion It remains to be elucidated in future studies whether monitoring of genetically influenced differences in cytokine gene regulation may be useful for preoperative selection or patients at high risk in septic situations for intensive monitoring or prophylactic treatment. Moreover it might be used to select patients for clinical trials utilizing anti-TNF strategies.

Postoperative fever and outcome in major surgery

R. G. Heemken, E. E. Forster and T. Hau, *Nordwest-Krankenhaus Sanderbusch, Sande, Germany*

Background This study determined whether fever is a predictor of outcome after major abdominal and thoracic surgery.
Methods A retrospective chart review of 179 patients who underwent major surgery (oesophagectomy, pneumonectomy, gastrectomy or colectomy) was performed. Demographic data, the operation performed, the nature of the underlying disease, transfusion requirements, daily temperature and white cell count

on the first 7 days after operation were recorded. Fever was defined as a temperature above 38·5°C.

Of the 179 patients 53 (29·6 per cent) developed fever and 126 (70·4 per cent) did not. The mortality rate in the first group was 23 per cent (12 of 53) and in the second group 4·0 per cent (five of 126). The overall mortality rate was 9·5 per cent (17 of 179). Logistic regression analysis showed that fever on days 5, 6 and 7 after operation was an independent predictor of outcome ($P < 0{\cdot}05$, $P < 0{\cdot}05$ and $P < 0{\cdot}01$ respectively).

Results

	Deaths			
	All	No fever	Fever	P^*
Elective procedures	8 of 133 (6·0)	3 of 103 (2·9)	5 of 30 (17)	0·01
Thoracic	4 of 71 (6)	1 of 58 (2)	3 of 13 (23)	
Upper gastrointestinal	3 of 24 (12)	1 of 15 (7)	2 of 9 (22)	
Lower gastrointestinal	1 of 38 (3)	1 of 30 (3)	0 of 8 (0)	
Emergency procedures	9 of 46 (20)	2 of 23 (9)	7 of 23 (30)	n.s.
All	17 of 179 (9·5)	5 of 126 (4·0)	12 of 53 (23)	< 0·001

Values in parentheses are percentages. $^*\chi^2$ test; n.s., not significant

	Mean temperature (°C)		
	Day 5	Day 6	Day 7
Survivors	37·2	37·1	37·1
Non-survivors	37·9	38·0	38·1
P^*	< 0·005	< 0·01	< 0·005

*Mann–Whitney *U* test

The most common causes of fever were pneumonia (14 patients), organ space infection (nine), urinary tract infection (eight) and wound infection (four).

Conclusion Fever in the late postoperative course (days 5–7 after operation) is an independent predictor of outcome after major abdominal and thoracic surgery.

Effect of continuous plasma filtration coupled with sorbent absorption in a model of Gram-negative sepsis

P. Bisagni, L. Gianotti, C. Tetta, M. Braga, R. Giardino, M. Fini and V. Di Carlo, *Department of Surgery, University of Milan, Rizzoli Institute, Bologna, Italy*

Background The treatment of Gram-negative sepsis is challenging. No clinical treatment has been shown to improve survival significantly. This study evaluated outcome and removal of mediators of sepsis using continuous plasma filtration (CP) coupled with sorbent absorption (SA) in a single-shot endotoxin model.

Methods New Zealand White rabbits were divided into four groups: CP only (group 1; $n = 10$); CP + endotoxin (0·05 mg per kg body-weight) (group 2; $n = 20$); CP + SA (group 3; $n = 19$); and CP + SA + endotoxin (group 4; $n = 19$). The sorbent device was composed of Amberchrome resin. Animals were treated for 180 min. Blood and plasma samples were obtained at 0, 60, 90, 120 and 180 min for determination of endotoxin, bioactive tumour necrosis factor (TNF) α and white blood cell (WBC) count. Mean arterial pressure (MAP) was monitored continuously and the 7-day mortality was recorded.

Results Mean(s.d.) endotoxin level was 1·1(0·9) ng ml^{-1} in group 2 *versus* 0·6(0·4) ng ml^{-1} in group 4. TNF at 90 min was 12(17) units ml^{-1} in group 2 and 26(39) units ml^{-1} in group 4. WBC count at 60 min was 3·4(1·6), 1·7(0·3), 4·9(0·5) and 2·3(0·8) per μl in groups 1, 2, 3, and 4 respectively ($P < 0{\cdot}05$, group 2 *versus* all). MAP at 60 min was 59(9), 36(10), 58(12) and 51(11) mmHg in groups 1, 2, 3 and 4 respectively ($P < 0{\cdot}05$, group 2 *versus* all). The mortality rate was 30, 75, 16 and 21 per cent in groups 1, 2, 3 and 4 respectively ($P < 0{\cdot}05$, group 2 *versus* all). Regardless of the type of treatment, the mean endotoxin level in surviving animals was lower than that in dying animals (0·5(0·4) *versus* 1·3(1·0) ng ml^{-1}; $P < 0{\cdot}05$).

Conclusion In this model of Gram-negative septic shock, the use of CP + SA significantly reduced the mortality rate. This effect may be mediated by the ability of the sorbent device to absorb endotoxin. This treatment also effectively counteracted the endotoxin infusion-mediated hypotension and leucopenia.

Hyaluronic acid solution decreases the healing of colonic anastomoses in rats with bacterial peritonitis

M. M. Reijnen, B. M. de Man, V. A. Postma, Th. Hendriks and H. van Goor, *Department of Surgery, University Hospital Nijmegen, Nijmegen, The Netherlands*

Background Hyaluronic acid (HA) reduces postsurgical adhesion formation. A reduction in intra-abdominal adhesion and abscess formation has been demonstrated in a rat peritonitis model using a 0·4 per cent HA solution. Prevention of adhesion formation might have adverse effects on the healing of fresh bowel anastomoses in normal individuals whereas the opposite is suggested for anastomotic healing in an infected environment. The influence of two HA agents on the healing of colonic anastomoses in normal rats and rats with bacterial peritonitis was investigated.

Methods In 72 male Wistar rats the caecum was dissected, ligated and punctured once at the antimesenteric site with a 19-G needle. After operation rats received one intramuscular dose of gentamicin 6 mg kg^{-1}. Twenty-four hours after laparotomy the abdomen was reopened and the caecum was resected. The descending colon was dissected and transected 3 cm proximal to the peritoneal reflection and an end-to-end anastomosis was performed (peritonitis group). In 60 male Wistar rats an end-to-end anastomosis of the colon was performed (control group). Animals in both groups were randomized to receive either a HA/carboxymethyl cellulose film (Seprafilm) (1 × 2 cm wrapped around the anastomosis and 2 × 2 under the midline incision), 8 ml 0·4 per cent HA solution (Sepracoat) or nothing (control subgroup). Half of the animals in each group were killed on day 3 and half on day 7 after operation, and the anastomosis was resected without adhesiolysis. Bursting pressures and breaking strengths were measured. Adhesions and abscesses were scored semiquantitatively.

Results During the experiment 11 rats died in the peritonitis group (15 per cent) and one rat in the control group (2 per cent). There was no significant difference in mortality rate between subgroups. In all subgroups both bursting pressures and breaking strengths were significantly higher on day 7 than day 3 ($P = 0{\cdot}0001$). On day 3 bursting pressures were significantly higher in rats with peritonitis compared with control rats in the HA/CMC subgroup ($P = 0{\cdot}01$) and the control subgroup ($P = 0{\cdot}006$) and not in the subgroup treated with HA solution. On day 7 there was no significant difference in bursting pressure between rats with peritonitis and controls. On both day 3 and day 7 rats with peritonitis treated with HA solution tended to have lower bursting pressures compared with untreated rats with peritonitis (159(17) *versus* 190(11) mmHg and 283(17) *versus* 315(17) mmHg, *P* not significant). There was no significant difference in breaking strengths measured at both time points between groups and subgroups. The lowest rate of intra-abdominal adhesions and abscesses was found in rats treated with the 0·4 per cent HA solution.

Conclusion Early healing of colonic anastomoses is enhanced in rats with bacterial peritonitis. This effect seems to be diminished by intraperitoneal treatment with HA solution.

Effect of carbon dioxide pneumoperitoneum on endotoxaemia, bacteraemia and interleukin 6 levels

H. Mersin, I. Sayek, D. A. Onat, D. Guc and S. Tuncer, *Department of General Surgery, Hacettepe University, School of Medicine, Ankara, Turkey*

Background Increased intra-abdominal pressure during laparoscopy may lead to bacteraemia and dissemination of infection. This study determined the effect of carbon dioxide pneumoperitoneum on endotoxaemia, bacteraemia and interleukin (IL) 6 levels in an animal model of intra-abdominal infection.
Methods Some 120 Swiss-Albino mice were divided into five experimental groups. Group 1 received a high intraperitoneal bacterial inoculum, consisting of a mean(s.d.) of $1{\cdot}2(0{\cdot}3) \times 10^8$ colony forming units (c.f.u.) per ml followed by laparotomy for 1 and 2 h in subgroups 3A and 3B respectively. Group 2 received a low intraperitoneal bacterial inoculum consisting of $1{\cdot}2(0{\cdot}3) \times 10^4$ c.f.u. ml^{-1} followed by laparotomy for 1 and 2 h in subgroups 2A and 2B respectively. Group 4 received an identical bacterial inoculum followed by carbon dioxide pneumoperitoneum for 1 and 2 h in subgroups 4A and 4B respectively. Group 5 received no bacterial challenge and was subjected to carbon dioxide pneumoperitoneum for 1 and 2 h in subgroups 5A and 5B respectively. Blood samples were taken at 30 and 60 min for measurement of plasma endotoxin levels and blood cultures, and at 60 min for IL-6 determination.
Results Endotoxin levels at 30 and 60 min were significantly higher in subgroup 3B compared with 1B ($P = 0{\cdot}007$, $P = 0{\cdot}02$). The differences in plasma endotoxin level at 30 and 60 min between other subgroups were not significant. There was no difference in serum IL-6 levels between all subgroups. There was a significant difference only in positive blood cultures at 60 min in subgroup 2A *versus* 4A ($P = 0{\cdot}007$). The differences in positive blood cultures between other subgroups were not significant.
Conclusion The results of this study suggest that pneumoperitoneum during severe intra-abdominal infection may aggravate endotoxaemia depending on the severity of infection and the duration of pneumoperitoneum.

Gastric tonometry, cytokines, anaesthesia and complications after colorectal surgery

F. G. Bergin, P. A. Mallinder, P. Royle, E. A. Garbett and D. J. Leaper, *Professorial Unit of Surgery, North Tees General Hospital, Stockton-on-Tees, UK*

Background The value of gastric tonometry, and interleukin (IL) 6 and tumour necrosis factor (TNF) α measurement in prediction of complications after elective colorectal surgery has been estimated.
Methods This was a prospective randomized study of four methods of anaesthesia, involving total intravenous anaesthesia with propofol, epidural and opiate analgesia.
Results Forty-five patients have been recruited so far. A significant advantage has already been accrued in patients having an epidural, being associated with shorter operations (median 126 (range 60–280) *versus* 180 (86–240) min; $P < 0{\cdot}01$), less blood loss (median 710 (range 200–2235) *versus* 1325 (250–2725) ml; $P < 0{\cdot}05$), better pain relief (83 *versus* 37 per cent; $P < 0{\cdot}02$) and a tendency to return home earlier. There was a steady rise in TNF-α levels after operation but IL-6 concentration peaked on the first postoperative day. Only IL-6 levels predicted postoperative complications (complications *versus* no complications: day 1, 200 (range 72–600) *versus* 97 (0–595) pg ml^{-1}, $P < 0{\cdot}05$; day 7, 49 (7–150) *versus* 11 (3–93) pg ml^{-1}, $P < 0{\cdot}002$). No similar association was found with TNF-α. There was a fall in gastric intramucosal pH (pH$_i$) during operations (median fall pH 0·08) but this had no relation to type of anaesthesia, blood loss, length of operation or the development of postoperative complications.
Conclusion Plasma levels of IL-6 can predict surgical complications after elective colorectal surgery. Gastric tonometry was unhelpful, which probably reflects good intraoperative anaesthetic practice.

Differential T helper 1 cell cytokine synthesis of human memory (CD45RO) *versus* naive (CD45RA) T cells following major burn trauma

S. Zedler, E. Faist, G. H. von Donnersmarck and F. W. Schildberg, *Department of Surgery, University of Munich and Burn Centre, Community Hospital Bogenhausen, Munich, Germany*

Background Based on patterns of expression of CD45 isoforms, T cells can be divided into functionally distinct and largely reciprocal subpopulations. The CD45RA-positive subset identifies primary (naive) T cells, while CD45RO cells are considered to be mostly primed (memory) T cells. It was hypothesized that under stressful conditions an excessive release of CD45RA-positive T cells should occur. It was the objective of this study to obtain further insight into the trauma-induced constitutional changes of proinflammatory cytokine patterns via analysis of CD45RA-positive and CD45RO-positive subsets in CD4-positive *versus* CD8-positive T cells. A newly developed technique of immunofluorescence was used to detect individual cytokine producing cells via flow cytometric analysis with monoclonal antibodies as specific reagents.
Methods Fifteen healthy controls and ten patients following major burn injury (mean(s.d.) age 39(5) years; mean(s.d.) Injury Severity Score 51(4)) had immunological screening on days 1, 5, and 7 after trauma. The *in vitro* capacity of peripheral blood mononuclear cells triggered with ionomycin (1 μmol l^{-1}) and phorbolester (5 ng ml^{-1}) to produce the T helper 1 cell cytokines interferon (IFN) γ and interleukin (IL) 2 was investigated.
Results

		Percentage of cytokine-positive cells			
T cell subset	Cytokine	Day 1	Day 5	Day 7	Control
CD4/45RO	IFN-γ	21·7(2·1)	20·0(1·2)‡	17·9(1·8)‡	26·6(1·5)
CD4/45RA	IFN-γ	2·2(0·3)†	2·4(0·5)*	3·3(0·8)†	1·0(0·2)
CD8/45RO	IFN-γ	41·4(7·3)	38·4(5·5)	41·1(5·2)	39·5(3·5)
CD8/45RA	IFN-γ	16·0(3·7)‡	16·5(3·3)‡	15·8(3·6)†	5·6(0·6)
CD4/45RO	IL-2	33·9(2·8)	35·5(7·4)	33·5(8·4)	38·9(2·2)
CD4/45RA	IL-2	8·3(1·4)†	15·6(6·7)	26·7(7·6)*	14·8(1·4)
CD8/45RO	IL-2	16·3(5·8)	25·3(8·2)*	26·7(7·6)*	9·7(1·6)
CD8/45RA	IL-2	6·8(1·8)*	18·6(10·2)*	10·7(1·8)†	1·4(0·4)

Values are mean(s.d.). *$P < 0{\cdot}05$, †$P < 0{\cdot}01$, ‡$P < 0{\cdot}001$ *versus* control

Conclusion These data demonstrate that helper (CD4 positive) as well as cytotoxic (CD8 positive) (naive) T cells (CD45RA positive) are capable of enhancing their IFN-γ synthesis under traumatic stress compared with those of healthy blood donors, while the IFN-γ response of the memory subtype (CD45RO positive) was diminished (CD4 positive) or remained unchanged (CD8 positive). The predominantly affected cellular source of IL-2 following burn trauma has been shown to be the CD8-positive CD45RA-positive lymphocyte. Further analysis of these data revealed that an augmented percentage of CD45RA-positive IL-2 and IFN-γ producing cells (compared with that in survivors) is predictive for non-survival after trauma. It is concluded that cytoplasmic T cell cytokine analysis represents a valuable screening method to predict biological aberrations and catastrophes.

Immunosuppressive effects of glycine on cytokine production of lipopolysaccharide-stimulated human blood monocytes

A. Spittler, C. Reissner, N. Manhart, R. Fuegger, G. Boltz and E. Roth, *Surgical Research Laboratories, University of Vienna, Vienna, Austria*

Background Monocytes play a central role in both specific and non-specific immunity against bacterial, viral and fungal infection. The non-essential amino acid glycine (GLY) has been shown to be protective against endotoxic shock in the rat. Since little is known about the influence of GLY on cytokine production by human monocytes, the role of GLY on monocytes from healthy donors was examined *in vitro* and *ex vivo*.

Methods Monocytes were isolated from 500 ml heparinized blood of healthy donors by counterflow centrifugation at a purity of about 85–95 per cent and cultured in RPMI 1640 medium with various concentrations of GLY (0, 0·13 (physiological concentration), 2, 5 and 10 mmol l^{-1}). To prevent cell activation monocytes were preincubated in Teflon dishes for 40 h. Afterwards monocytes were stimulated with lipopolysaccharide (LPS) 1 μg ml^{-1}; supernatants were collected after 1, 6, 12, 24, 48 and 72 h and measured for tumour necrosis factor (TNF) α and interleukin (IL) 10 by enzyme-linked immunosorbent assay. Whole blood assays (blood from healthy donors) were performed using heparinized vacutainer tubes. Blood was preincubated for 6 h with GLY (plasma concentration 1 and 2 mmol l^{-1}) and subsequently treated with LPS 1 μg ml^{-1}. Supernatants were analysed for TNF-α, IL-β and IL-10 after 1, 3, 6 and 12 h of LPS treatment.

Results Stimulation of purified monocytes with LPS led to maximum production of TNF-α after 6 h which was dose dependently reduced by increasing the GLY concentration in the culture medium (2 mmol l^{-1}, −40 per cent; 10 mmol l^{-1}, −89 per cent; $P<0·01$). The effect of IL-10 after LPS stimulation was time dependent. A high GLY load caused an increased IL-10 production (+304 per cent) 6 h after LPS stimulation, but blocked IL-10 production after 24 h (−56 per cent) after LPS stimulation. In a similar manner, whole blood LPS stimulation reduced TNF-α concentration ($P<0·01$) as well as IL-β level ($P<0·05$) with GLY 2 mmol l^{-1} by 3 h. IL-10 production was significantly enhanced 6 h after LPS stimulation ($P<0·05$).

Conclusion These data demonstrate that GLY affects cytokine production of monocytes in the direction of immunosuppression.

Preoperative immunotherapy with interleukin 2 and infective complications in colorectal surgery

A. Nespoli, F. Brivio, P. Gramazio, M. Castolid and G. Gariboldi, *Third Surgical Clinic, Universita degli Studi of Milano, San Gerardo Hospital, Monza, Italy*

Background The immunological response is essential in controlling postoperative infections and normal repair of surgical wounds. It is necessary to increase the immune response in oncological colorectal surgery in the hope of controlling neoplastic cells and reducing infective complications which are frequent in this kind of surgery. The incidence of infective complications was evaluated in patients undergoing elective colorectal surgery with or without preventive treatment with interleukin (IL) 2. Patients with occlusion, perforation and bleeding, second tumours, past or present steroid therapy and patients older than 80 years were excluded.

Methods In the treated group there were 40 patients, of mean age 60·3 (range 36–80) years. IL-2 immunotherapy was 9 000 000 units twice a day for 3 days in the preoperative period. The control group included 73 consecutive patients, of mean age 65·6 (range 36–80) years, undergoing elective surgery in the same period but without immunological therapy. All patients received the same intestinal preparation and prophylaxis with cefoxitin.

Results There was one postoperative death from stroke in the treated group and no surgical deaths in the control group. There were a number of infective complications after surgery. One of 40 patients in the IL-2 group developed sepsis (pelvic infection) and five (7 per cent) of 73 in the control group (one associated with complete anastomotic wound leakage and three with intraperitoneal sepsis). One of 40 in the IL-2 group developed a wound infection (the patient with sepsis) and 12 (16 per cent) of 73 in the control group ($P=0·0032$). One of 40 patients in the IL-2 group suffered anastomotic leakage of radiological but not clinical significance and two (3 per cent) of 73 in the control group (one associated with sepsis). Other associated infections were four of 40 *versus* seven (10 per cent) of 73 in the lungs and three of 40 *versus* four (5 per cent) of 73 in the urinary tract.

Conclusion IL-2 is a specific T lymphocyte growth factor, although it induces secretion of other cytokines in a cascade sequence which involves all the immune cells and particularly the macrophage. This activation has a positive role in tissue repair and infection control. The only real risk is an overproduction of IL-6 and tumour necrosis factor by the activated macrophage which induces multiorgan failure syndrome. With the IL-2 dosage currently used and in the authors' clinical experience this possibility is theoretical, while a significant reduction in surgical infection occurs.

Imaging experimental intra-abdominal abscesses with technetium-99m-PEG-liposomes and technetium-99m-HYNIC-immunoglobulin G

M. M. P. J. Reijnen, E. Th. M. Dams, W. J. G. Oyen, O. C. Boerman, G. Storm, P. Laverman, J. W. M. van der Meer, F. H. M. Corstens and H. van Goor, *Departments of Nuclear Medicine, Surgery and Internal Medicine, University Hospital Nijmegen, Nijmegen, and Utrecht University, Utrecht, The Netherlands*

Background Rapid and accurate localization of intra-abdominal infection remains a challenging problem for nuclear imaging techniques. Two newly developed technetium-99m-labelled agents, technetium-99m-PEG-liposomes and technetium-99m-HYNIC-immunoglobulin (Ig) G, have shown excellent imaging of experimental focal infection, but have not yet been studied in the detection of abdominal abscesses. Liposomes are particularly attractive, as they offer the opportunity for targeted drug delivery. The performance of these two agents was studied in a rat model of intra-abdominal infection; gallium-67-citrate was included as a reference agent.

Methods On day 0, intra-abdominal infection was induced in rats by caecal ligation and puncture. The following day, the caecum was resected and the abdominal cavity was rinsed with normal saline. On day 8, rats were randomized and injected intravenously with technetium-99m-PEG-liposomes, technetium-99m-HYNIC-IgG or gallium-67-citrate ($n=12$ in each group). Rats were imaged at regular intervals for 24 h. After the final image at 24 h after injection, rats were killed and the uptake of the radiolabel in dissected tissues was determined. Macroscopic abnormalities and focal uptake on the images were scored semi-quantitatively.

Results Some 85 per cent of rats showed intra-abdominal abscess formation. Abscesses were clearly delineated by the three agents from 4 h after injection. Liposomes, IgG and gallium-67 all showed high absolute uptake in the abscess (mean(s.d.) 2·3(0·3), 2·8(0·3) and 2·8(0·4) per cent ID g^{-1} respectively), and did not differ significantly. Focal uptake of all three radiopharmaceuticals correlated well with the severity of inflammation (for liposomes $r=0·65$, $P<0·03$; for IgG $r=0·61$, $P<0·05$; for gallium-67 $r=0·73$, $P<0·02$).

Conclusion Technetium-99m-labelled PEG-liposomes and technetium-99m-HYNIC-IgG show high focal uptake in experimental intra-abdominal abscess, similar to the standard agent gallium-67. The uptake correlated well with macroscopic inflammation. The lower radiation exposure and more favourable physical properties of technetium-99m make labelled liposomes and IgG attractive agents for imaging abdominal infection. In addition, PEG-liposomes could be valuable in the treatment of abdominal inflammation by enhanced local delivery of incorporated drugs.

Correlation between antithrombin III levels and outcome and severity of diffuse peritonitis

A. Woltmann, C. Eckmann, K. H. Staubach and H. P. Bruch, *Department of Surgery, Medical University Lubeck, Lubeck, Germany*

Background Coagulopathy is a frequent complication in diffuse peritonitis. Endotoxin initiates the coagulation cascade. Subse-

quently, the consumption of anticoagulative factors leads to severe coagulopathy and plays a major role in septic organ failure.
Methods The correlation between antithrombin III (AT-III) levels and the severity and outcome of diffuse peritonitis was studied retrospectively in 88 patients. The severity of peritonitis was determined by the Mannheim Peritonitis Index (MPI), the Acute Physiology And Chronic Health Evaluation (APACHE) II score and the Sepsis Severity Score (SSS).
Results At the onset of the intra-abdominal infection, a severe decrease in AT-III level was noted to a mean of 62 per cent in survivors and 57 per cent in non-survivors. On day 1, the AT-III levels in patients with scores of less than 20, 20–30 and greater than 30 were 69, 61 and 57 per cent (MPI), 62, 60 and 55 per cent (APACHE II day 1), and 74, 56 and 56 per cent (SSS day 1) respectively. The lowest AT-III levels were 52 per cent in survivors and 45 per cent in non-survivors ($P<0\cdot05$), and for the above-mentioned severity groups 55, 49 and 47 per cent (MPI), 53, 48 and 42 per cent (APACHE II day 1), and 61, 49 and 44 per cent (SSS day 1) respectively. The differences between the SSS and APACHE II groups with scores of less than 20 and greater than 30 were significant ($P<0\cdot05$). The respective AT-III values were measured before substitution.
Conclusion These results indicate that there are correlations between AT-III levels, and outcome and severity of peritonitis.

Shoemaker criteria as a prognostic marker for postoperative morbidity and mortality

M. Poeze, G. Ramsay, J. W. M. Grieve and J. Takala, *Department of Surgery, Academic Hospital Maastricht, Maastricht, The Netherlands and Department of Intensive Care Medicine, Kuopio University Hospital, Kuopio, Finland*

Background The Shoemaker high-risk criteria have been proposed to predict postoperative morbidity and mortality in surgical patients. This study was designed to evaluate prospectively the usefulness of these criteria as a prognostic marker.
Methods In a prospective study, patients undergoing abdominal, non-vascular surgery were screened before operation for the number of Shoemaker criteria present (from a list of 13 criteria). At 24 h an Acute Physiology And Chronic Health Evaluation (APACHE) II and multiple organ failure (MOF) score were calculated and correlated with the Shoemaker criteria, using the Pearson correlation coefficient. The survival at day 28 was related to the number of Shoemaker criteria present using log rank analysis, Cox multiple regression analysis, and receiver–operator characteristic (ROC) curves.
Results Some 433 patients were assessed, of whom 412 were evaluable. The majority (52 per cent) had only one criterion. An increasing Shoemaker score was related to an increased mortality rate, calculated by log rank analysis. The presence of shock and respiratory failure were the most important criteria calculated by regression analysis. The mean(s.d.) area under the ROC curve was 0·72(0·04) for predicting death. The correlation coefficients of the Shoemaker score related to the APACHE II score and the MOF score were 0·308 ($P<0\cdot001$) and 0·305 ($P<0\cdot001$) respectively.
Conclusion The Shoemaker criteria can be used as a quick preoperative prognostic marker for identification of high-risk surgical patients. However, no clear relation exists with the severity scores during the first 24 h after operation.

Treatment of *Candida* peritonitis

P. Kujath, C. Boos and C. Eckmann, *Department of Surgery, Medical University Lubeck, Lubeck, Germany*

Background *Candida* peritonitis is a severe disease with a high associated mortality rate. The management of these critically ill patients is still a matter of debate.
Methods Since 1980 all patients with diffuse peritonitis were treated by daily relaparotomy and abdominal lavage. During surgical intervention, aspirates of fluid and samples of peritoneum were obtained. The clinically suspected diagnosis of invasive mycosis was verified by histological examination. Patients received either fluconazole (initially 800 mg followed by 400 mg daily) or amphotericin B and flucytosine (0·5–1 mg per kg body-weight). At the time of infection of the first four patients effective antimycotics were not available. The course of infection was followed from peritoneal samples taken during relaparotomy.
Results Some 265 patients with diffuse peritonitis were treated. The infection was caused by *Candida* spp. in 19 cases (7·1 per cent). The mean(s.d.) age of these patients was 59·4(24·8) years; there were 11 men and eight women. Seventy-nine abdominal lavages were performed. The isolates were *C. albicans* ($n=13$), *C. tropicalis* ($n=3$), *C. glabrata* ($n=2$) and *C. pulcherrima* ($n=1$). Antifungal treatment included application of fluconazole ($n=9$) or amphotericin B and flucytosine ($n=6$). Resolution of infection occurred in 15 cases. Four patients did not receive antimycotics. Eight patients survived.
Conclusion A deep invasive mycosis of the abdominal cavity can be resolved by aggressive surgical intervention in combination with antimycotic substances. Treatment with fluconazole is as effective as application of amphotericin B and flucytosine. The substantially reduced general condition of the patients leads to high mortality rates despite resolution of infection.

Surgical treatment of acute purulent mediastinitis

A. E. Krein, K. Neukam and O. Elert, *Department of Cardiovascular and Thoracic Surgery, Wurzburg University, Wurzburg, Germany*

Background Purulent mediastinitis can occur as a complication of oropharyngeal and cervical infections or after open heart surgery. Delayed diagnosis and inadequate drainage are the main causes of a high published mortality rate (up to 50 per cent).
Methods The primary management of purulent mediastinitis in this institution includes partial or complete sternotomy, withdrawal of all foreign bodies, radical debridement of the mediastinum and, if necessary, revision of the pericardium and pleural space. A massive dose of broad-spectrum antibiotics is given and modified according to the microbiological results. The second step of treatment is an open programmed irrigation with daily revision and debridement. Intensive care monitoring and ventilation are needed.
Results During a period from 1986 to 1996 11 patients (nine men; aged from 24 to 71 years) with purulent mediastinitis were treated. Aetiology was a descending necrotizing mediastinitis because of oropharyngeal infection in five cases and there were six postoperative infections after open heart surgery (coronary artery bypass graft, aortic valve replacement). Microbiological features included *Streptococcus* spp., *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Candida albicans*, *Enterobacter* spp. and nocardiosis. Intensive care unit stay was from 2 days up to 6 months. Four of the 11 patients died. One patient died from myocardial infarction with low cardiac output syndrome and three patients developed multiorgan failure due to generalized sepsis.
Conclusion Active surgical intervention can improve the clinical outcome of patients with purulent mediastinitis. Unfortunately, a high mortality rate remains and mediastinitis is still a life-threatening condition.

Computed tomography: a vital adjunct in the management of complex postoperative abdominal sepsis

C. A. Harris, D. A. Nicholson and I. D. Anderson, *Intestinal Failure and Nutrition Unit, Hope Hospital, Salford, UK*

Background Clinical diagnosis of complex postoperative abdominal sepsis is made difficult by previous surgery and by complications such as organ failure, line sepsis, fistulas or malnutrition, but it is established that recovery is unlikely if abdominal sepsis continues. This unit provides a national tertiary referral

service for these patients. A 2-year prospective evaluation of the use of routine admission abdominal computed tomography (CT) to detect previously unidentified abdominal sepsis is reported.
Methods Early abdominal CT with gastrointestinal contrast enhancement was performed in 32 instances in 28 patients admitted to the unit with suspected abdominal sepsis from October 1995. Median patient age was 49 (range 22–75) years and 26 fulfilled Bone's criteria for sepsis. CT identified abdominal collections in 21 of 32 instances but failed in five of 32; in the latter cases collections were detected at laparotomy performed for failure of conservative treatment. After six of 32 scans patients were treated conservatively with success.
Results Immediate radiological drainage was performed with clinical benefit in 11 of 21 cases and surgical treatment was necessary only in a further five of 21 patients in whom radiological drainage was not appropriate (multiple or inaccessible collections). In five of 21 cases, small superficial collections connected to draining fistulas were managed conservatively. CT revealed radiologically drainable abdominal collections on three of 31 occasions in patients who did not satisfy the Bone criteria for sepsis.
Conclusion Abdominal CR detects previously unrecognized collections in two-thirds of patients transferred for further management of the complications of abdominal surgery; radiological drainage is sufficient in a majority of these. A low threshold for CT and drainage should be maintained in patients following complicated abdominal surgery.

In vitro improvement of transendothelial migration of polymorphonuclear neutrophils in patients with cirrhosis by granulocyte colony stimulating factor

C. Fiuza, B. Herrera, M. Salcedo, G. Clemente and J. M. Tellado, *Surgical Infections Unit, HGU Gregorio Maranon, Madrid, Spain*

Background Patients with cirrhosis present with a high incidence of bacterial infections. They have a deficient cell influx towards infective sites. This study assessed neutrophil adhesion and transendothelial migration *in vitro* and evaluated the possible immunostimulatory effect of granulocyte colony stimulating factor (G-CSF).
Methods Polymorphonuclear neutrophil (PMN) adhesion and transendothelial migration was studied in patients with cirrhosis ($n = 14$) and healthy controls ($n = 14$) using the microvascular endothelial cell line HMEC-1. PMNs were isolated from whole blood by density gradient centrifugation and labelled with the fluorescent dye BCECF-AM. For adhesion assays, 10^5 PMNs per well were co-incubated for 1 h with resting or tumour necrosis factor (TNF) α-stimulated HMEC-1 cells. Unattached cells were removed and the number of adherent PMNs per well was calculated with a microtitre plate fluorimeter. For migration experiments, 2×10^5 PMNs were added into a Transwell system over TNF-α-stimulated endothelium and allowed to migrate for 2 h in response to FMLP in the lower chamber. Then, transmigrated PMNs were harvested and counted. G-CSF 100 ng ml^{-1} was added to neutrophils at the start of the assay and was present throughout.
Results Mean(s.d.) neutrophil adhesion was increased in patients with cirrhosis compared with controls to both resting (18·9(7·2) $\times 10^3$ *versus* 10·8(3·0) $\times 10^3$ PMNs per well; $P < 0·01$) and TNF-α-stimulated (27·7(7·1) $\times 10^3$ *versus* 18·6(6·1) $\times 10^3$ PMNs per well; $P < 0·01$) HMEC-1 cells. G-CSF significantly increased PMN adhesion in controls but not in patients with cirrhosis. Neutrophil transendothelial migration was decreased in patients with cirrhosis (36·5(15·5) $\times 10^3$ PMNs per well) compared with controls (60·2(23·3) $\times 10^3$ PMNs per well) ($P < 0·01$). G-CSF significantly enhanced neutrophil transmigration both in patients with cirrhosis (44·4(17·7) $\times 10^3$ PMNs per well) and in healthy controls (71·5(27·3) $\times 10^3$ PMNs per well) ($P < 0·01$).
Conclusion G-CSF enhances neutrophil transendothelial migration in patients with cirrhosis despite having no effect on neutrophil adhesion. This suggests that G-CSF is able to increase neutrophil recruitment into local infective sites in these patients.

Type II diabetes intensifies the response to intestinal ischaemia–reperfusion

J. Arias-Diaz, J. C. Garcia-Perez, A. Cortes, P. Gonzalez, E. Vara and J. L. Balibrea, *Departments of Biochemistry, Surgery and Research Unit (Hospital San Carlos), UCM, Madrid, Spain*

Background It has been shown that granulocytes isolated from diabetic patients display a greater degree of activation than those from non-diabetics. In addition, both type I and type II diabetes are associated with increased lipid peroxidation and higher levels of circulating adhesion molecules. Neonatal streptozotocin (STZ) administration in rats leads to mild insulin deficiency in adults with normal blood glucose levels, and is accepted as a model of type II diabetes. In this study possible differences in the systemic release of some inflammatory mediators after intestinal ischaemia–reperfusion (I–R) between control and type II diabetic rats were investigated.
Methods STZ 0 or 30 mg kg^{-1} was injected into Wistar rats on the day of birth. Two-month-old animals, both control and type II diabetic (normoglycaemic), were randomly separated into two groups. Group 1 rats underwent a 60-min period of gut ischaemia by clamping the superior mesenteric artery. Five minutes after reperfusion, rats were killed and plasma samples were obtained from portal vein (PV), and infrahepatic (IHC) and suprahepatic (SHC) cava. Group 2 rats underwent sham operation. Nitric oxide was measured as NO_2^- and NO_3^- by the Griess reaction. Lipid hydroperoxides (LPO) were determined spectrophotometrically using a commercially available kit. Tumour necrosis factor (TNF) α, 75-kDa receptor (TNF-R2), 60-kDa receptor (TNF-R1) and intercellular adhesion molecule (ICAM) 1 were measured by enzyme-linked immunosorbent assay.
Results After I–R, diabetic rats showed increased plasma concentrations of LPO, nitric oxide, ICAM-1 (mean(s.d.) 0·514(0·083) *versus* 0·046(0·011) ng ml^{-1} (IHC); 0·574(0·075) *versus* 0·037(0·009) ng ml^{-1} (SHC); and 0·528(0·067) *versus* 0·033(0·009) ng ml^{-1} (PV); $n = 10$, all $P < 0·01$), TNF-α (42·4(5·7) pg ml^{-1} (IHC), 248·4(28·2) pg ml^{-1} (SHC) and 33·6(4·0) pg ml^{-1} (PV) in diabetic rats *versus* undetectable in control rats; $n = 10$), TNF-R1 (0·179(0·024) *versus* 0·023(0·011) ng ml^{-1} (IHC); 0·233(0·032) *versus* 0·033(0·005) ng ml^{-1} (SHC); 0·206(0·034) *versus* 0·039(0·023) ng ml^{-1} (PV); $n = 10$, all $P < 0·05$) whereas TNF-R2 did not differ between groups. Both TNF-α and nitric oxide plasma levels were higher in SHC than in IHC and PV after I–R, pointing to the liver as an important source for both mediators.
Conclusion Pre-existing type II diabetes intensifies the inflammatory response after intestinal I–R.

Kinetics of tumour necrosis factor α, interleukins 1β, 6, 8 and 10, phospholipase A_2 and neopterin in surgical treatment of diffuse peritonitis: results of bedside monitoring

A. Hunsicker, L. Wilhelm, D. Lorenz, J. Petermann and W. Weissenhofer, *Departments of Surgery, University of Greifswald, Germany and Rudolfinerhaus Wien, Austria*

Background This study evaluated cytokine and mediator kinetics during primary and scheduled surgical interventions in treatment of patients with diffuse peritonitis to establish bedside monitoring.
Methods Eleven patients with necrotizing pancreatitis (median Ranson score 7 (range 6–8)) and one patient with postoperative peritonitis underwent 19 operations combined with preoperative intraoperative and postoperative sequential blood sampling. Serum concentrations of tumour necrosis factor (TNF) α, interleukins (ILs) 1β, 6, 8 and 10, neopterin and phospholipase A_2 (PLA_2) were measured.

Results Detectable ETX concentrations were less than 4 units ml^{-1} in all measurements; the highest values were found before operation. TNF-α concentration increased at operation to a median (interquartile range) of 58·5 (28·2–92·8) pg ml^{-1} with a similar postoperative course (53·8 (10·0–104·0) pg ml^{-1}. IL-1β level rose at operation to 15·6 (3·6–17·8) pg ml^{-1} ($P<0{\cdot}05$). IL-6 was increased in all postoperative samples, and was maximal after 3·5 h (1327 (550–2020) pg ml^{-1}; $P<0{\cdot}05$). High levels of IL-8 were seen at operation after 1·5 h (72 (43–142) pg ml^{-1}; $P<0{\cdot}05$) and 2 h (121 (55–157) pg ml^{-1}; $P<0{\cdot}05$) and IL-8 expression increased again after operation to a maximum (183 (72–299) pg ml^{-1}; $P<0{\cdot}05$) after 3·5 h. IL-10 showed a preoperative peak level (49·7 (6·9–168·0) pg ml^{-1}) and at operation was 22·6 (11·8–89·8) pg ml^{-1} ($P<0{\cdot}05$). PLA$_2$ was pathologically high continuously, but not significantly so. Neopterin showed highest concentrations (72·0 (35·0–86·2) nmol l^{-1}; $P<0{\cdot}05$) during operation. Rescheduled operation appeared to have no influence on long-term cytokine course. Some 12 h before operation IL-6 correlated with Acute Physiology And Chronic Health Evaluation (APACHE) II score ($r=0{\cdot}55$, $P<0{\cdot}05$). Significant correlations were found between TNF-α concentration and IL-6 expression ($r=0{\cdot}67$, $P<0{\cdot}01$). IL-6 level correlated significantly with IL-8 expression ($r=0{\cdot}67$, $P<0{\cdot}01$). There were correlations between IL-10 expression and IL-6 concentration ($r=0{\cdot}95$, $P<0{\cdot}001$) and IL-8 values ($r=0{\cdot}63$, $P<0{\cdot}02$). Early intraoperative (first 15 min) IL-10 level correlated with IL-6 expression ($r=0{\cdot}96$, $P<0{\cdot}001$). After 30 min, IL-8 level correlated with IL-6 expression ($r=0{\cdot}61$, $P<0{\cdot}05$) and IL-20 values ($r=0{\cdot}64$, $P<0{\cdot}05$). The correlation between IL-6 concentration and IL-10 expression persisted into the early postoperative period (3 min) ($r=0{\cdot}94$, $P<0{\cdot}001$). In the third hour after operation TNF-α values correlated with the time span of operation ($r=0{\cdot}63$, $P<0{\cdot}05$). There was a prolonged correlation between IL-8 concentration and IL-10 expression ($r=0{\cdot}60$, $P<0{\cdot}03$).

Conclusion In the surgical treatment of critical care patients, established scoring systems like APACHE II can be supplemented with the response of the proinflammatory and anti-inflammatory activities of cytokines. Bedside monitoring based on cytokines could be established in daily clinical routine. However, because of the financial and personal costs, interdisciplinary and multicentre cooperation is necessary.

Experimental study of the effect of nitric oxide inhibition on mesenteric blood flow and interleukin 10 levels in endotoxin challenge

A. Baykal, B. Kavuklu, A. Iskit, O. Guc, G. Hascelik and I. Sayek, *Department of General Surgery, Hacettepe University School of Medicine, Ankara, Turkey*

Background The effects of two nitric oxide synthase (NOS) inhibitors, L-NAME and aminoguanidine (AG), on mesenteric blood flow (MBF) and interleukin (IL) 10 levels in lipopolysaccharide (LPS) challenge were evaluated.

Methods Swiss albino mice were divided into two groups (pretreatment and post-treatment). In the pretreatment group, at 0 h animals were injected with AG 20 mg kg^{-1}, L-NAME 20 mg kg^{-1} or saline. At 20 min saline was injected into half of the animals and LPS 10 mg kg^{-1} was injected into the other half. At 140 min a perivascular Doppler ultrasonic probe was placed around the superior mesenteric artery to measure MBF. Following this, blood samples were drawn for measurement of IL-10 levels. In the post-treatment group, at 0 h LPS 10 mg kg^{-1} or saline was injected. At 20 min, AG 20 mg kg^{-1}, L-NAME 20 mg kg^{-1} or saline was injected. At 120 min, the procedures described above were repeated.

Results In both pretreatment and post-treatment groups LPS significantly decreased MBF in the saline group ($P<0{\cdot}001$ and $P<0{\cdot}0002$ respectively). Both NOS inhibitors were effective in preventing this decrease, administered as either pretreatment or post-treatment when compared with corresponding saline groups ($P<0{\cdot}05$ for any combination). Post-treatment with either NOS inhibitor did not prevent the decrease when compared with the saline–saline group ($P=0{\cdot}0069$ *versus* LPS–AG and $P=0{\cdot}0015$ *versus* LPS–L-NAME) whereas pretreatment was also effective ($P<0{\cdot}05$ for both). In both pretreatment and post-treatment groups LPS significantly increased IL-10 levels compared with those in the corresponding saline groups ($P<0{\cdot}05$ for any combination). In the pretreatment groups, comparison of LPS groups showed that the mean IL-10 level in the saline–LPS group was significantly lower than that in the L-NAME–LPS group ($P=0{\cdot}011$). In the post-treatment animals there was no significant difference between the three LPS groups.

Conclusion NOS inhibition before LPS challenge prevents the subsequent decrease in MBF and increases IL-10 levels, but inhibition after LPS challenge is not effective. L-NAME is more powerful in increasing IL-10 levels than AG.

Adrenaline tolerance and endotoxin tolerance differentially modulate serum cytokine levels to lipopolysaccharide challenge in a murine model

A. Baykal, V. Kaynaroglu, G. Hascelik, I. Sayek and Y. Sanac, *Department of General Surgery, Hacettepe University School of Medicine, Ankara, Turkey*

Background Cytokines are the primary mediators of sepsis syndrome. Adrenaline tolerance increases survival in endotoxic shock models. In this study, the effect of adrenaline and endotoxin tolerance on major cytokine levels in lipopolysaccharide (LPS) challenge was determined.

Methods Adrenaline tolerance was developed by injecting adrenaline 0·01 mg kg^{-1} to Swiss albino mice, gradually increasing the dose to 2 mg kg^{-1} over 5 days. Endotoxin tolerance was developed by injecting saline for 4 days and LPS 1 mg kg^{-1} on the fifth day. Control animals were injected with saline for 5 days. Some 72 h after completion of injections, saline was injected into half of the animals in each group and LPS 20 mg kg^{-1} into the other half. Peak serum levels of tumour necrosis factor (TNF) α, (IL) 1β, IL-6, IL-10 and IL-12 were assayed and compared.

Results LPS injection significantly raised the levels of all the cytokines studied in the control and adrenaline-tolerant animals ($P<0{\cdot}05$ for any cytokine). TNF-α, IL-6 and IL-10 levels were significantly lower in endotoxin-tolerant animals than in saline controls after LPS challenge ($P<0{\cdot}05$ for any cytokine). Interestingly, adrenaline-tolerant animals had significantly higher levels of TNF-α, IL-6 and IL-12 than saline controls in response to LPS challenge ($P<0{\cdot}05$ for any cytokine). Neither adrenaline tolerance nor endotoxin tolerance induced a significant change in IL-1β levels in response to LPS ($P>0{\cdot}05$ for any combination).

Conclusion Adrenaline tolerance primes for an exaggerated release of TNF-α, IL-6 and IL-12 in response to LPS challenge, demonstrating the anti-inflammatory and immunosuppressive roles of adrenaline. Anti-inflammatory effects are not mediated through increased IL-10 release. Endotoxin tolerance selectively modulates cytokine release. The results also suggest that IL-1β might have different regulatory mechanisms than the other cytokines studied.

Effects of extracorporal endotoxin removal on liver haemodynamics in a porcine sepsis model

M. Schindl, U. Windberger, D. Falkenhagen, R. Resch, B. Paul, H. Bergmeister, K. Kaczirek, R. Auer, T. Sautner, R. Fugger and U. Losert, *Centre of Biomedical Research and Department of Surgery, University of Vienna, Vienna, Austria*

Background Endotoxin-induced activation of macrophages followed by release of cytokines and inflammatory mediators has profound effects on liver blood flow and microvascular permeability. Disturbance of liver blood circulation is one of the major events aggravating the early phase of sepsis. This study investigated the effects of extracorporeal bacterial endotoxin absorption (microsphere-based detoxification system, MDS) on liver blood circulation in a porcine sepsis model.

Methods In 14 Landrace pigs (mean body-weight 24 kg), bacterial endotoxin (*Escherichia coli* lipopolysaccharide (LPS) $20\,\mu g\,kg^{-1}\,h^{-1}$) was infused intravenously over 3 h. Liver haemodynamics were determined by measurement of portal venous blood flow, hepatic and portal vascular pressures and liver surface microcirculation (laser Doppler flowmetry). Liver portal vascular resistance was calculated. LPS levels in hepatic venous and arterial blood were determined using *Limulus* amoebocyte lysate. In animals in the therapy group ($n = 8$), an extracorporal endotoxin absorption system based on macroporous cellulose beads with immobilized polyethylenimine (MDS) was used to remove LPS from the circulation.
Results LPS infusion resulted in an initial increase in portal vascular resistance of 26·1 per cent with a simultaneous drop in portal venous blood flow and liver surface microcirculation to 85·5 and 62·2 per cent of baseline respectively ($P < 0{\cdot}05$). Over time, a recovery of portal venous blood flow and hepatic microcirculation was found above baseline until the end of the experiment. The initial drop and the following increase in portal venous blood flow and liver microcirculation were more pronounced in the control group compared with the MDS group. Endotoxin plasma values from arterial and venous blood samples varied widely during LPS infusion in the control and MDS group with marked reduction in the latter.
Conclusion Bacterial endotoxaemia led to a profound disturbance of liver haemodynamics, characterized by a biphasic alteration in liver vascular resistance and surface microcirculation. Extracorporal endotoxin elimination by MDS attenuated endotoxin-induced changes in local liver microcirculation possibly by reducing the LPS-mediated inflammatory response.

Supplemental perioperative oxygen administration increases subcutaneous oxygen tension

O. Plattner, R. Fugger, F. Tayefeh, O. Akca, F. Lackner, C. Arkilic, A. Kurz, D. I. Sessler and H. Hopf, *Departments of Anaesthesia and Surgery, University of Vienna, Vienna, Austria and University of California, San Francisco, California, USA*

Background Surgical wound infections are common and serious perioperative complications. The major defence against surgical pathogens is oxidative killing by neutrophils. Consequently, the incidence of infection correlates with subcutaneous tissue oxygen tension. The extent to which increasing inspired oxygen tension augments tissue oxygen tension in clinical practice remains unclear. Accordingly, the hypothesis that administration of supplemental perioperative oxygen increases subcutaneous oxygen tension was tested in surgical patients.
Methods Forty patients undergoing colonic resection were studied. They were randomly assigned to 30 per cent ($n = 24$) or 80 per cent ($n = 16$) inspired oxygen (balance nitrogen). Oxygen administration at the designated concentration was continued for 2 h after operation with an AirCare sealed mask system (Apotheus Laboratories, Lubbock, Texas, USA). Arterial partial pressure of oxygen was determined after 1 h of anaesthesia and after 2 h of postoperative recovery. Subcutaneous oxygen tension was recorded from a polarographic electrode (Licox Medical Systems, New York, USA) positioned within a silicone tonometer on the upper arm.
Results Intraoperative arterial oxygen tension was significantly greater in patients given 80 per cent than 30 per cent oxygen (mean(s.d.) 372(107) *versus* 147(40) mmHg). Postoperative arterial oxygen tension was also significantly greater: 188(122) *versus* 112(34) mmHg respectively. Mean intraoperative and postoperative tissue oxygen tensions were also significantly greater during administration of 80 per cent than 30 per cent oxygen (intraoperative 124(46) *versus* 60(28) mmHg; postoperative 72(25) *versus* 53(30) mmHg).
Conclusion These data indicate that supplemental oxygen administration increases tissue oxygen tension from levels associated with frequent infections to levels at which infections are rare.

Intraoperative prophylaxis in patients at risk: a prospective study in colonic surgery

O. Neun and H. Wacha, *Department of Surgery, Academic Hospital of the University of Frankfurt, Frankfurt, Germany*

Background Antimicrobial prophylaxis is particularly effective in colonic surgery. Wound infection rates of about 10 per cent after elective colonic resection are expected. The administration of antibiotics at induction of anaesthesia is most commonly used. In clinical practice there is evidence that the time interval between the first dose, the time of contamination and subsequent infection is uncertain.
Methods A study was therefore conducted in 100 patients undergoing colorectal surgery by giving the first dose of antibiotics during the operation. The study included all types of colonic surgery (for obstruction, diverticulitis and abscesses). Bowel preparation did not include antibiotics. The mean age was 70 years; 95 per cent had an American Society of Anesthesiologists score above 3. The first dose of mezlocillin 4 mg and metronidazole 500 mg was administered 32 (range 5–120) min after the abdominal incision. The operations lasted 146 (range 40–265) min. The second and last dose was given 6–8 h later. Early postoperative feeding was started the day after operation.
Results There were two patients with a postoperative fever above 38°C, six wound infections of the abdominal incision, one anastomotic leakage and no deaths. The mean postoperative stay was 18 (range 7–54) days.
Conclusion In surgical practice there is considerable variation in the timing of the prophylactic administration of antibiotics. The authors therefore propose intraoperative administration as the safest method to reduce bacterial postoperative complications in patients at risk.

Human β-defensin expression in burned and uninjured skin

S. M. Milner, M. R. Ortega, J. O. Kucan and M. W. Neumeister, *Institute for Plastic and Reconstructive Surgery, Southern Illinois University, USA*

Background Defensins are a family of cationic antimicrobial peptides which are part of a non-specific chemical defence system secreted by non-lymphoid cells. Two human β-defensins have been identified. Human β-defensin 1 (hβD-1) has been detected in urogenital, gastrointestinal and pulmonary epithelia, but not in skin. Human β-defensin 2 (hβD-2) is produced by keratinocytes and is the only antimicrobial peptide that has been identified in human skin. Both β-defensins have potent bactericidal activity against a wide spectrum of Gram-positive, Gram-negative and fungal organisms, including *Escherichia coli*, *Pseudomonas*, *Staphylococcus* and *Candida*. The combination of the loss of skin barrier, and failure of both local and systemic immunity, predisposes the burn patient to an increased risk of infection.
Methods Expression of hβD-1 and hβD-2 in the wound of eight patients with full-thickness burns was examined. At the time of wound excision, samples were obtained from each patient for measurement of hβD-1 and hβD-2 expression from both the burn wound and from normal skin. Total RNA was isolated, purified and then subjected to reverse transcriptase–polymerase chain reaction for hβD-1, hβD-2 and three control genes.
Results Single bands representing hβD-1 and hβD-2 expression were found in normal skin; however, only hβD-1 was identified in full-thickness burn wounds. Expression of the control genes was found in both the burn wounds and in normal skin.
Conclusion It is proposed that β-defensins play a protective role in preventing infection within burn wounds and that altered expression of these peptides could promote local overgrowth of micro-organisms. The broad antimicrobial properties of defensins, their chemical resistance and their lack of antigenicity

suggest that they may also be useful as antimicrobial agents for prophylaxis and treatment of burn wound infections.

Surgical intervention in patients with methicillin-resistant *Staphylococcus aureus*

C. Eckmann, C. Boos and P. Kujath, *Department of Surgery, Medical University Lubeck, Lubeck, Germany*

Background The worldwide spread of methicillin-resistant *Staphylococcus aureus* (MRSA) had led to important therapeutic problems. The optimal timing for surgical treatment in these patients is still uncertain.
Methods All patients with microbiological evidence of MRSA were followed consecutively in this department. The analysis of data included history, previous and concomitant medication, and microbiological and clinical course. After isolation of MRSA, all patients with signs of infection were treated for 5–10 days with antibiotics shown to be sensitive by antibiogram accompanied by daily anti-infective washing of the skin. During infection, surgical procedures were performed under antibiotic medication. After antibiotic treatment follow-up was done by taking swabs of different body areas every 3 days. The infection was resolved when MRSA was not isolated any more in three following swab collections.
Results Between 1 January 1994 and 30 September 1997, 60 cases of MRSA infection occurred. The mean(s.d.) age of the patients was 64·1(11·9) years; there were 34 men and 26 women. MRSA was frequently isolated in tracheal aspirate ($n = 44$), skin ($n = 26$), wound area ($n = 21$), blood culture ($n = 9$) and drains ($n = 4$). Twenty-five patients underwent surgical procedures during or shortly after the infection with MRSA: amputation ($n = 14$), mesh graft transplantation ($n = 5$), laparotomy ($n = 4$) and thoracotomy ($n = 2$). In ten cases the infection spread into the surgically treated area; six of these patients died and in four patients the infection resolved.
Conclusion Surgical intervention in patients with MRSA is associated with a high rate of infection of the surgically treated areas. Elective surgery in these patients should be avoided.

Synchronous appearance of high interleukin 6 plasma concentrations and low responsiveness of peripheral blood cells to lipopolysaccharide following surgical trauma

C. Denzel, J. Riese, C. Mehler, M. Zowe, W. Hohenberger and W. Haupt, *Department of Surgery, University of Erlangen, Erlangen, Germany*

Background The mechanisms of postoperative immunosuppression are not completely understood. Changes in cytokine production (interleukin (IL) 6, tumour necrosis factor (TNF) α, IL-10) were investigated in whole blood of patients who had major abdominal operations and the results were related to the immediate immune response to surgical trauma determined by measuring plasma IL-6 concentrations.
Methods Heparinized blood was drawn from 40 patients before the operation, 6 h after skin incision and on the third day after operation. From five patients blood samples were also collected at 1, 2, 3, 4 and 5 h after skin incision. Lipopolysaccharide (LPS) 10 ng ml^{-1} was added and samples were incubated at 37°C and 5 per cent carbon dioxide. Cytokine concentrations in the plasma were assayed (TNF-α and IL-6 after 5 h, IL-10 after 24 h of incubation) by enzyme-linked immunosorbent assay (IL-6 and TNF-α at all time points, IL-10 before operation and on day 3). Serum IL-6 was measured by the Immulite technique. IL-6 messenger RNA (mRNA) was assessed by reverse transcriptase–polymerase chain reaction in peripheral blood mononuclear cells 5 h after skin incision.
Results Production of TNF-α and IL-6 after stimulation with LPS decreased significantly in whole blood drawn 6 h after skin incision and increased on postoperative day 3. The mean(s.d.) consecutive values were 10 686(9403), 3601(4560) and 7029(12 049) pg ml^{-1} for TNF-α, and 78 798(41 451), 21 710(20 299) and 32 247(31 232) pg ml^{-1} for IL-6. IL-10 decreased from 8914(12 242) pg ml^{-1} before operation to 4557(4185) pg ml^{-1} at day 3. A decrease in TNF-α and IL-6 production was already seen at 2 h following skin incision. Serum IL-6 concentrations were increased at 6 h following skin incision from 14(36) to 1071(1570) pg ml^{-1}, peaked at 12 h at 1522(2266) pg ml^{-1} and decreased subsequently to 99(108) pg ml^{-1} at day 3. At 5 h, no IL-6 mRNA was found in circulating blood cells.
Conclusion The capacity of the whole blood to produce cytokines (IL-6, TNF-α, IL-10) was reduced immediately after surgical trauma. In parallel an immediate immune response was found as indicated by high plasma IL-6 concentrations. Circulating IL-6 was not produced by blood cells in response to surgical trauma.

Automated entry of surgical site infection surveillance data: use of an optical scanning system

T. M. Smyth, G. McIlvenny and J. M. Hood, *The Royal Hospitals, Belfast, UK*

Background A project was instituted to monitor continuously the incidence of surgical site infection (SSI) in the Surgical Directorate of The Royal Hospitals, Belfast, UK.
Methods Employing optical scanning technology (Formic for Windows version 2.0; Formic, London, UK) a SSI questionnaire was designed which included relevant data modelled on the National Nosocomial Infections Surveillance System for Surgical Site Infections, including the SSI risk index (Hospital Infections Program; Centers for Disease Control, Atlanta, Georgia, USA). Staff of the surgical directorate were responsible for completion of the questionnaires. Infection control staff with the assistance of 'link' nurses coordinated the surveillance. Scanning of completed questionnaires was followed by data processing for validation and correction of errors. Accuracy rates of 99·98 per cent were achieved with this system. The contents of the database were then exported to SPSS software (SPSS, Chicago, Illinois, USA) for analysis.
Results A total of 7666 surgical procedures was recorded (January 1995 to December 1997). The crude SSI rate for all procedures was 2·8 per cent. The SSI rate for clean, clean-contaminated, contaminated and dirty surgery was 1·2, 4·2, 7·0 and 15·0 per cent respectively. Some 26·6 per cent of patients were shaved before operation. SSI rates for shaved and non-shaved patients were 1·9 and 2·0 per cent respectively. Consultant surgeons had lower crude SSI rates (2·6 per cent) compared with senior registrars (4·5 per cent). When the SSI rates were refined using the SSI risk index, the rates were 1·0 per cent, 1·4 per cent (index 0); 4·4 per cent, 6·9 per cent (index 1); and 8·6 per cent, 21·1 per cent (index 2) for consultants and senior registrars respectively. The same trend was observed whether the surgery was elective or emergency.
Conclusion The use of optical scanning technology to process completed surveillance questionnaires automatically has allowed continuous monitoring of SSI in this hospital. This methodology is recommended to those involved with surveillance of nosocomial infections as a method of removing the bottleneck of manual data entry. In addition to general surgery, this system is being employed in cardiac surgery and neurosurgery.

Staphylococcus aureus infection in serious burns: review of 2700 admissions

A. T. McManus, E. Greenfield and C. W. Goodwin, *US Army Institute of Surgical Research, Fort Sam, Houston, Texas, USA*

Background In recent years at most burn centres, the combination of improved methods of patient care and the practice of isolation of seriously burned patients has resulted in a decreased incidence of infection and in particular of wound infection. Associated with this observation has been a change in pathogens from previously common *Pseudomonas aeruginosa* and other Gram-negative organisms to increases in Gram-positive offenders. The incidence of *Staphylococcus aureus* colonization and infections has been reviewed in consecutive patients admitted to a single burn centre between 1986 and 1997.

Methods Patients were cared for in single-bed isolation rooms during the intensive care phase of treatment. Patients were assigned to specific nursing care teams during each working day and cross-team care was prohibited. Microbial surveillance, consisting of wound surface, sputum amd urine cultures three times weekly, was carried out on patients from admission to discharge. Colonization was defined as isolation from noninfected site and infection was defined using site-specific criteria. Predominant organisms in each culture were subjected to antibiotic sensitivity testing. Oxacillin resistance was used to define *S. aureus* strains resistant to β-lactam antibiotics (methicillin-resistant *S. aureus*, MRSA). Demonstration of MRSA colonization or infection did not alter isolation practices.

Results *S. aureus* colonization was observed in 1220 admissions (45 per cent). *S. aureus* caused 391 infections in 275 patients (10 per cent). The respiratory tract was the most common site (63 per cent). *S. aureus* infections represented 31 per cent of all infections during the period. *S. aureus* was the most common pathogen identified and was more than twice as frequent as the next cause of infection. MRSA colonization was identified in 360 patients (13 per cent). Most MRSA infections occurred in 112 patients (4 per cent). The mortality rate in *S. aureus*-infected patients was not greater than that predicted on the basis of severity of injury and age. MRSA infection did not change this finding.

Conclusion These results identify *S. aureus* as the principal pathogen in this cohort. MRSA colonization or infection was not found to cause outcomes different from those of colonization or infection with oxacillin-sensitive strains.

Alterations in bacterial flora after large bowel surgery over the time of drainage

M. Drews, R. Marciniak, M. Lange, W. Michalska and J. Chylak, *Departments of Surgery and Medical Microbiology, University School of Medical Sciences, Poznan, Poland*

Background This study analysed the bacterial flora colonizing drains after large bowel surgery with special regard to the qualitative changes of bacterial flora and to the dynamics of development of bacterial strain resistance.

Methods Forty-two patients who underwent large bowel surgery using a closed drainage system were examined. Specimens from each patient were taken three times: a smear from the peritoneal cavity during operation, a sample from the drain taken on day 3 after surgery and another sample from the drain at the end of drainage.

Results From 126 specimens, 159 aerobic and 59 anaerobic bacterial strains were cultured. Aerobes only were isolated from 62 specimens (49·2 per cent), mixed bacterial flora from 37 (29·4 per cent), and anaerobes only from nine (7·1 per cent). Eighteen specimens (14·3 per cent) gave no growth. The composition of bacterial isolates from patients was analysed. There was a significant decrease in the number of isolated anaerobic bacteria, from eight (19 per cent) to zero, and an increase in the number of aerobic bacteria, from 12 (29 per cent) to 30 (71 per cent) ($P < 0{\cdot}05$). During the three successive examinations there was an increased frequency of isolation of coagulase-negative staphylococci, from nine to 24 strains; and from eight to 16 and from none to three strains of *Enterococcus faecalis* and *Candida albicans* respectively. The number of cultured strains of *Escherichia coli* decreased from eight to one and of *Bacteroides* spp. from 24 to three. The frequency of isolation of methicillin-resistant coagulase-negative staphylococci increased significantly from one to 14 and the increase was clearly connected to the time of drainage and duration of hospital stay before operation. The same bacterial species were isolated twice or more often from 27 patients. More than one bacterial species were isolated from nine patients during two or three successive examinations. The sensitivity of the cultured bacterial species to antibiotics was tested; cephalosporins showed low activity against aerobic bacteria (20·1–28·1 per cent) and the resistance of *Enterococcus* spp. and *Staphylococcus* spp. was 90 and 50 per cent respectively.

Conclusion Prolonged drainage can cause retrograde infections, often related to environmental pathogens.

Antibiotic therapy in surgical intra-abdominal infection: piperacillin–tazobactam *versus* cefotaxime plus metronidazole – a multinational study

W. K. J. Huizinga, S. Karran, J. Lange, A. Wildisen, A. J. Torres and K. Schultheis, *Department of Surgery, University of Natal, South Africa*

Background Surgical intra-abdominal infection is a life-threatening condition requiring swift diagnosis, operative intervention and antimicrobial therapy. It results from disruption of the gastrointestinal tract in trauma and intra-abdominal disease. As culture data are not available initially, the antibiotic therapy has to be empirical and effective against the polymicrobial microflora, the great majority of which produce β-lactamase. This study compared the efficacy and safety of piperacillin, tagged to the β-lactamase inhibitor tazobactam, with the combination of cefotaxime and metronidazole in intra-abdominal infections.

Methods A randomized comparative multicentre study involving 364 patients with intra-abdominal infections requiring surgery was conducted by 23 centres in 11 countries. Patients received intravenously every 8 h either piperacillin 4 g with tazobactam 500 mg (P/T) or cefotaxime 2 g plus metronidazole 500 mg (C + M). Assessment of overall condition on entry into the study, and clinical and bacteriological responses at the end of treatment and follow-up were made.

Results Patients in the two groups were comparable in demographics, severity of disease, site of origin of the infection and operative intervention. Many patients had sustained trauma, including gunshot wounds and stab wounds. The overall mortality rate was 9·1 per cent ($n = 33$), 8·6 per cent in the P/T group ($n = 16$) and 9·5 per cent in the C + M group ($n = 17$). Death with sepsis occurred in 3·2 per cent ($n = 6$) of patients having P/T and 2·8 per cent ($n = 5$) of those receiving C + M. Clinical cure and improvement was evident in 94·8 and 90·4 per cent respectively ($P = 0{\cdot}22$). The bacterial response was satisfactory in 94·7 per cent of patients having P/T and 95·2 per cent of those receiving C + M (*P* not significant). Overall, both treatments were highly effective in microbial eradication. Adverse reactions, mainly nausea, vomiting, diarrhoea and rash, were comparable and minor.

Conclusion P/T is at least as effective and safe as C + M for the treatment of surgical intra-abdominal infection. It has the advantage of monotherapy, requiring less complex dosing schedules, which is important in busy surgical wards.

Use of teicoplanin and granulocyte colony stimulating factor in experimental methicillin-resistant *Staphylococcus aureus* pneumonia

N. Oz, C. Agalar, C. Daphan, F. Agalar and R. Turkyilmaz, *Department of Infectious Diseases, SKK Hospital and Department of Emergency Medicine, Hacettepe University, Ankara, Turkey*

Background The effects of teicoplanin and/or granulocyte colony stimulating factor (G-CSF) on survival in an animal model of methicillin-resistant *Staphylococcus aureus* (MRSA) pneumonia were evaluated.

Methods Seventy-five male Swiss albino mice weighing 35 (range 32–43) g were used. Some 50 μl of a clinical isolate of MRSA (3×10^8 colony forming units per ml in saline solution) was administered by tracheal puncture in neutropenic mice. Neutropenia was achieved by using cyclophosphamide 200 mg per kg intraperitoneally. Mice were divided into five groups: group 1, tracheal puncture control in neutropenic mice ($n = 15$); group 2, pneumonia in neutropenic mice ($n = 15$); group 3, teicoplanin therapy for pneumonia in neutropenic mice ($n = 15$); group 4,

G-CSF therapy for pneumonia in neutropenic mice ($n = 15$); group 5, teicoplanin and G-CSF combined therapy for pneumonia in neutropenic mice ($n = 15$).
Results Teicoplanin therapy increased the survival rate ($P = 0{\cdot}0001$) whereas G-CSF therapy did not. Teicoplanin and G-CSF combined therapy improved the survival rate in comparison to that in groups 2, 3 and 4 ($P = 0{\cdot}0001$, $P = 0{\cdot}003$ and $P = 0{\cdot}0001$ respectively).
Conclusion Teicoplanin and G-CSF combined therapy seems effective in reducing mortality rates in MRSA pneumonia in experimental conditions.

Value of prophylactic antibiotic therapy in severe acute pancreatitis: unicentre prospective study

Ch. Muller, W. Uhl and M. W. Buchler, *Department of Visceral and Transplantation Surgery, University Hospital of Bern, Bern, Switzerland*

Background Infected pancreatic necrosis (IPN) is the main cause of death in severe acute pancreatitis. The role of prophylactic antibiotic therapy in preventing infectious complications was investigated in a prospective clinical trial.
Methods Some 139 patients (86 men) with acute pancreatitis were admitted from November 1993 to September 1997; mean age was 55 (range 25–87) years. Severe acute pancreatitis was proven by contrast-enhanced computed tomography in 62 patients (45 per cent) with a varying extent of necrosis. The remaining 77 patients (55 per cent) suffered from mild or oedematous acute pancreatitis. All patients with severe acute pancreatitis ($n = 62$; mean Ranson score, Acute Physiology And Chronic Health Evaluation II score and C-reactive protein level at admission were 4·0 (range 1–10), 15·5 (range 6–28) and 191 (range 12–334) mg l^{-1} respectively) were transferred to the intensive care unit (ICU) and antibiotic therapy using intravenous imipenem–cilastatin was administered for 14 days at a dosage of 0·5 g three times daily. Fine-needle aspiration was undertaken for Gram staining and culture; a positive result was the indication for operative intervention.
Results Twenty-two (35 per cent) of 62 patients developed IPN after a mean of 27 (range 10–44) days and were operated on during the course of antibiotics. The following organisms were found: *Staphylococcus* spp. in 48 per cent, *Candida* in 38 per cent, *Enterococcus* spp. in 24 per cent, *Escherichia coli* in 19 per cent, *Klebsiella* spp. in 19 per cent and other bacteria in 24 per cent. In all other patients surgery was not indicated. ICU stay in patients with sterile necrosis was 6 (range 1–18) days and in those with IPN and operation 38 (range 3–152) days. The overall mortality rate in patients with severe acute pancreatitis was 6·5 per cent (four of 62); two of 40 patients with sterile necrosis died and two of 22 with IPN.
Conclusion This long-term therapy with imipenem–cilastatin in severe acute pancreatitis is effective in reducing the infection rate and delaying operation to the third week with optimal surgical conditions with an overall mortality rate below 10 per cent. However, further studies are necessary to determine the optimal length of antibiotic therapy and the risk of mycotic infection.

Effectiveness of an intervention programme in reducing postoperative infection and improving the quality and cost of antimicrobial use in a digestive surgical unit

M. Merle-Melet, F. Marchal, J. M. Tortuyaux, B. Hanessa, M. A. Hoffman, B. Legras, L. Bresler and P. Boissel, *Digestive Surgical Unit, Chirurgie Pharmacie and d'Anesthesie-Reanimation, Vandoeuvre, France*

Background Since 1995, postoperative infections and surgical risk factors have been recorded continuously according to the Centers for Disease Control recommendations for infection control. Written protocols were defined in elective surgery, except for hernia surgery, according to the recommendations of the French Society of Anaesthesia and Intensive Care.
Methods In 1995, baseline infection rates were assessed in 1510 patients. In 1996, some modifications were made in antibiotic prophylaxis regimens, according to identified risk factors, and guidelines were defined in emergency, hernia and proctological surgery. Cefoxitin was preferred in colorectal surgery, and cefamandole was preferred in biliary and gastroduodenal surgery.
Results

Surgery	Wound infection rate (%)	Adequate antimicrobial prophylaxis (%)	Length of hospital stay (days)*	Benefit (days of hospital stay)
Colorectal				
1995 ($n = 327$)	24·8	88	15·6(10·1)	
1996 ($n = 322$)	19·3	96	14·9(7·2)	161
Gastroduodenal				
1995 ($n = 124$)	14·5	62	14·3(9·3)	
1996 ($n = 163$)	3·7	71	13·2(9·1)	163
Abdominal hernia				
1995 ($n = 91$)	24·2	—	13·2(9·5)	
1996 ($n = 122$)	9·8	76	10·5(4·8)	367

Values are mean(s.d.)

In 1996, a total of 1607 patients were recorded with an 11·1 per cent wound infection rate compared with 16·3 per cent in 1995 ($P < 0{\cdot}001$). Length of postoperative stay was reduced or equivalent. A benefit of at least 712 days of hospital stay was obtained with the most appropriate use of antimicrobial prophylaxis (*Table*). Guidelines for the use of antibiotics in therapy were distributed to surgeons and anaesthesiologists in 1995. Since July 1996, a restrictive policy to limit inadequate use of antibiotics has been in place. Physicians could prescribe all antibiotics. However, three levels (I, II, III) were distinguished, requiring approval of the infection control practitioner, respectively at day 7, 5 and 3 of the prescription. Analysis was made in terms of number of days of antibiotic treatment (DTAB = grams of antibiotics consumed divided by the defined daily dose). A significant reduction ($P < 0{\cdot}001$) of DTAB was observed during the last period. DTAB of quinolones dropped from 2741 days in 1995 to 1666 days in 1996, and DTAB of fluconazole dropped from 990 days in 1995 to 401 days in 1996, despite the comparable incidence of postoperative nosocomial infections. Consequently, the cost of the antibiotic treatment was reduced by 17·8 per cent in 1996 with comparable efficacy.
Conclusion Surgical units which are multidisciplinary could benefit by having infection control practitioners to reduce the cost of antimicrobial treatment.

Elution of six antibiotics bonded to Dacron vascular grafts sealed with three proteins: *in vitro* study

M. Kitzis, J. O. Galdbart and C. Branger, *Hôpital Beaujon, Clichy, France*

Background The elution six antistaphylococcal antibiotics from vascular Dacron grafts sealed with albumin, collagen or gelatin was studied. The antibiotics tested were fusidic acid, pefloxacin, pristinamycin, rifampin, teicoplanin and vancomycin.
Methods The grafts were impregnated by simple soaking. The data were fitted to an exponential model and antibiotic half-lives ($t_{\frac{1}{2}}$) were calculated from the regression lines.
Results All the antibiotics tested were bound to the protein sealants. Antibiotic release varied with the type of antibiotic and the sealant. Rifampin was eluted most slowly, particularly with albumin- and gelatin-sealed grafts with a $t_{\frac{1}{2}}$ of 4–5 h and antibiotic activity still found at 48 h. The glycopeptides were also eluted slowly but there was no residual activity at 24 h.
Conclusion *In vitro* studies can be useful for evaluating antibiotic binding to protein-sealed grafts. It can be tested in animals or humans as local antimicrobial prophylaxis graft implantation in vascular surgery.

Bacteriology of multiple intra-abdominal fluid collections in acute pancreatitis

I. Pulay, M. K. Thege, A. Zsirka, Z. Csapo, A. Magyar and L. Flautner, *Semmelweis University School of Medicine and National Institute of Public Health, Hungary*

Background The complicated form of acute pancreatitis frequently produces multiple necrotic foci in the pancreas and fatty tissues in the peripancreatic spaces. Secondary infection of these foci is an important prognostic factor for these patients. Surgical intervention and effective adjuvant antibiotic treatment can decrease infection-related complications and reduce the mortality rate. The antibiotic therapy selected at the time of initial intervention should cover aerobic and anaerobic bacteria. Refinement of antibiotic coverage should be based on the culture result of samples obtained at operation.

Methods A prospective study was performed during 1995–1996 to investigate the pathogens in multiple abscesses and fluid collections in patients operated on for infected pancreatic necrosis.

Results Some 171 samples were collected during 76 operations on 69 patients and analysed bacteriologically. The mean number of samples per patient was 2·1. The cultures were positive in 159 cases (93 per cent) and negative in 12 cases (7 per cent). Fifty-six different species were cultured, of which 17 were Gram-negative (mainly Enterobacteriaceae), 19 Gram-positive (mostly enterococci) and 19 anaerobes. The pathogens were the same in each sample in 13 interventions (17 per cent), and were different (either the species or the sensitivity of isolates) at 63 operations (83 per cent). It has been shown that separate fluid collections could be infected with various pathogens.

Conclusion These data suggest that the anti-infective therapy of these patients should be based on the results of multiple samples taken during operation.

Oral ofloxacin in perioperative prophylaxis in abdominal surgery

M. Schwarz, R. Isenmann, P. Ebeling and H. G. Beger, *Department of General Surgery, University of Ulm, Ulm, Germany*

Background Antibiotic prophylaxis in abdominal surgery is recommended in patients with colonic resection or in patients undergoing extensive surgery. In aseptic surgery antibiotic prophylaxis is reserved for patients with a high infection risk. In a prospective study serum and tissue concentrations of oral ofloxacin were measured in order to provide a pharmacokinetic basis for oral prophylaxis.

Patients Patients were given ofloxacin 400 mg orally 2 h before surgery. Plasma and tissue concentrations of ofloxacin were measured by high-pressure liquid chromatography. Patients were divided into a low-risk group (ten patients having inguinal hernia repair and ten patients undergoing cholecystectomy) and a high-risk group (ten patients undergoing colonic resection and ten pancreatic resection).

Results Ofloxacin was administered a median of 145 (range 70–315) min before surgery. The median time for the surgical procedure was 170 (range 25–510) min. Median ofloxacin serum level at the beginning of the operation was 3·2 (interquartile range 2·6–4·4) mg l^{-1} and at the end of surgery 2·7 (1·8–3·5) mg l^{-1}. Tissue concentrations are listed in the *Table*.

Ofloxacin	Hernial sac	Gallbladder	Colon	Pancreas
Tissue concentration (mg l^{-1})	2·7 (1·7–3·6)	7·9 (4·9–12·3)	5·1 (4·6–7·3)	6·6 (3·8–7·1)
Tissue : serum ratio	1·1 (0·5–1·3)	2·8 (1·4–3·8)	1·9 (1·5–2·2)	2·6 (1·7–5·0)

Values are median (interquartile range)

The half-life of ofloxacin was median 305 min, total clearance 188 ml min^{-1} and volume of distribution 117 litres. Oral ofloxacin achieves high serum and tissue concentrations throughout surgical procedures where administered 2 h before operation.

Conclusion Pharmacokinetic data show that perioperative prophylaxis with oral ofloxacin is a low-cost alternative to intravenous prophylaxis. The effectiveness of oral prophylaxis should be investigated in controlled studies.

Translocation of different strains of enteric bacteria in an *ex vivo* model

R. Isenmann, M. Schwarz, E. Rozdzinski, R. Marre and H. G. Beger, *Departments of General Surgery and Medical Microbiology and Hygiene, University of Ulm, Ulm, Germany*

Background Passage of enteric bacteria through the intact intestinal mucosa is an initial step in the pathogenesis of abdominal sepsis. In this study, the ability of different enteric bacterial species to cross the intact colonic mucosa was examined in an *ex vivo* model.

Methods The colon of 15 male Wistar rats was removed; the colonic mucosa was dissected free and placed in a modified Ussing system consisting of eight chambers. The mucosal reservoir of each chamber was filled with 2 ml of a suspension of bacteria (concentration ranging from $3{\cdot}8 \times 10^7$ to $5{\cdot}8 \times 10^8$ colony forming units (c.f.u.) per ml) in Dulbecco's Modified Eagle Medium (DMEM), whereas the serosal side was filled with sterile DMEM. Samples were drawn from the serosal side at 0, 1, 2, 3 and 4 h after the start of the experiment and plated on agar plates allowing selective growth. After 18 h of incubation, c.f.u. were counted. Concentrations of more than 100 c.f.u. ml^{-1} on the serosal side were considered positive for translocation. The following bacterial strains were investigated: *Enterococcus faecalis* OG1X, *E. faecalis* OG1X:pAM721, *E. faecalis* INY 3000, *Salmonella typhimurium* ATCC BV VI and *Escherichia coli* Hb 101.

Results Within 4 h, *S. typhimurium* was detected on the serosal side in 12 of 15 experimental settings. None of the three strains of enterococci nor *E. coli* Hb 101 was found positive for translocation (*E. faecalis* OGIX, seven experiments; *E. faecalis* OG1X:pAM721, seven experiments; *E. faecalis* INY 3000, eight experiments; *E. coli* Hb 101, 13 experiments).

Conclusion These results show that bacterial translocation is a species-dependent process. *S. typhimurium* ATCC BV VI is able to translocate across intact rat colonic epithelium within 4 h whereas the enterococci tested as well as *E. coli* Hb 101 are not. The results are consistent with the clinical observation that infections with enterococci occur in the later phase of abdominal sepsis.

Stroke volume *versus* cardiac output as a marker for predicting postoperative morbidity

M. Poeze, G. Ramsay, J. W. M. Grieve and M. Singer, *Department of Surgery, University Hospital, Maastricht, The Netherlands and Bloomsbury Institute of Intensive Care Medicine, University College London, London, UK*

Background A significant peroperative tissue oxygen debt appears to predispose to subsequent complications including organ dysfunction. Whether this can be detected in the immediate postoperative period by using either absolute levels or trends in stroke volume (SV) and cardiac output (CO) remains to be ascertained. This study investigated whether non-invasive monitoring of SV and CO by oesophageal Doppler ultrasonography could be used as prognostic parameters in patients undergoing cardiac surgery.

Methods Twenty patients admitted to the intensive care unit following cardiac surgery, and apparently haemodynamically stable, were enrolled. An oesophageal ultrasound probe (ODM 2; Abbott, UK) was inserted for measurement of SV and CO. These and routine haemodynamic variables (mean arterial pressure (MAP), central venous pressure (CVP), heart rate

(HR), arterial base deficit (sBE), urine output and core–toe temperature difference) were recorded. Forty per cent underwent emergency coronary artery bypass grafting (CABG) and 60 per cent routine CABG and/or valve replacement. Nine patients developed postoperative complications and two died.
Results Significant differences ($P<0{\cdot}05$) were seen between complicated and uncomplicated cases for SV, sBE and HR at admission, but not for CO. The area under the receiver–operator characteristic curve was significantly higher for SV than for HR or sBE ($P<0{\cdot}01$). The risk of morbidity after cardiac surgery was significantly related to low SV, high HR and raised sBE but not to CO. A compensatory tachycardia maintains CO in apparently haemodynamically stable patients. It may be postulated that a low SV (secondary to hypovolaemia or poor myocardial function) plus additional sympathetic stimulation may be injurious. This process can best be monitored by measuring SV.
Conclusion SV is a useful marker for morbidity after cardiac surgery.

Diffuse peritonitis in an obstetric and gynaecological intensive care unit: causes and treatment

V. Milenkovic, S. Vrzic, M. Petronijevic, J. Milovanovic and A. Gudovic, *Department of Obstetrics and Gynaecology, Clinical Centre of Serbia, Belgrade, Yugoslavia*

Background Causes and treatment of diffuse peritonitis in an obstetric and gynaecological intensive care unit were examined.
Methods During a 2-year period in this intensive care unit 17 patients with diffuse peritonitis of different origin were treated. Most of them (11) had a pre-existing tubo-ovarian abscess; there were also cases of tubo-ovarian abscess and appendicitis (two patients), tubo-ovarian abscess and paralytic ileus, infection after caesarian section, subtotal abdominal hysterectomy and vaginal hysterectomy. The mean age of the patients was 44 (range 18–68) years. Surgical treatment was performed when indicated and 22 operative procedures were undertaken. Most frequently performed were total abdominal hysterectomy with bilateral adnexectomy in eight of the 17 patients and adnexectomy in three patients. Other surgical procedures included appendicectomy, intestinal resection, hysterectomy with conservation of the ovaries, salpingectomy, resection of the ovaries and extirpation of an abscess capsule. In all cases adhesiolysis and drainage was performed.
Results Purulent material obtained from the operative field after microbiological analysis presented various bacterial flora, with a predominance of *Escherichia coli* (25 per cent), *Streptococcus α haemolyticus*, *Pseudomonas* spp., *Acinetobacter*, *Staphylococcus aureus* and *Staphylococcus epidermidis* (10 per cent), *Streptococcus β haemolyticus*, *Bacteroides* spp., *Enterococcus*, *Klebsiella* and anaerobic bacilli (5 per cent). High doses of broad-spectrum antibiotics were given during the postoperative period. All of these patients were discharged from the hospital except one with a pulmonary embolus.
Conclusion Diffuse peritonitis is a relatively rare but severe condition in obstetric and gynaecological practice. With removal of infective foci and adequate antibiotic therapy most cases of severe inflammatory disease can be cured.

Antibiotic resistance of pathogens cultured from multiple intra-abdominal fluid collections

A. Zsirka, M. K. Thege, I. Pulay, Z. Csapo, A. Magyar and L. Flautner, *Semmelweis University School of Medicine and National Institute of Public Health, Hungary*

Background The bacteriology and antibiotic resistance of infective agents in multiple intra-abdominal fluid collections and abscesses due to necrosis of pancreas were studied prospectively.
Methods A total of 171 samples representing different fluid collections and abscesses were taken from 69 patients at 76 operations (2·1 samples per patient).
Results Enterobacteria were the most frequent pathogens, and were present in 40·7 per cent of 329 isolates belonging to 56 species, but the predominance of *Escherichia coli* was not significant (*E. coli* 13 per cent, *Bacteroides* spp. 11 per cent, *Enterococcus* spp. 11 per cent, *Klebsiella* spp. 10 per cent, *Pseudomonas aeruginosa* 10 per cent, *Enterobacter* spp. 8 per cent, *Streptococcus* spp. 7 per cent). Resistance rates were analysed for antibiotics that were used widely for the treatment of patients with infected necrosis of the pancreas. Ceftazidime resistance was frequent among Gram-negative bacteria: *E. coli* 7 per cent, *Klebsiella* spp. 24 per cent, *Enterobacter* spp. 58 per cent, *Citrobacter* spp. 50 per cent, *P. aeruginosa* 9 per cent. In contrast, imipenem resistance occurred only in *Enterobacter* spp. (8 per cent) and in *P. aeruginosa* (10 per cent) of the Gram-negative organisms. Ciprofloxacin showed no activity against 6–42 per cent of enterobacteria and 28 per cent of *P. aeruginosa*. Amikacin resistance rates ranged from 3 per cent (*E. coli*, *P. aeruginosa*) to 27 per cent (*Enterobacter* spp.), while gentamicin frequently proved ineffective. Ampicillin and high-level gentamicin resistance occurred frequently among enterococci (30 and 66 per cent respectively), but only two of 33 isolates were vancomycin resistant. Cefoxitin was the least active antianaerobic agent.
Conclusion The high resistance rates suggest that the nosocomial pathogens play an important role in the superinfection of necrotic pancreatic tissues. Consequently, antibiotic therapy should be based on the bacteriological results obtained from representative, multiple, peroperative specimens.

Pathophysiological parameters of knee-joint effusions in the absence and presence of infection

P. Cathrein, H. P. Simmen, T. Hug, J. Romero, C. Gerber and J. Blaser, *Orthopaedic University Hospital, Zurich, Balgrist Regional Hospital, Oberengadin, Samedan, and University Hospital, Zurich, Switzerland*

Background The metabolic activity of bacterial pathogens and host defence activity may often alter milieu factors, such as pH, partial pressure of oxygen P_{O_2} and partial pressure of carbon dioxide P_{CO_2} at the site of infection. Studies performed in peritoneal fluid revealed significant differences in these variables between infected and non-infected specimens. Furthermore, altered milieu factors are known to influence antibiotic activity. To verify such observations in joints, 56 samples of knee-joint effusions were analysed.
Methods Patients over 18 years of age suffering from knee-joint effusions were enrolled. Effusions were sampled immediately before arthroscopic or other operative procedures for diagnostic as well as therapeutic reasons. The measurements were completed within 5 min after sampling using a radiometer ABL 505. Knee-joint effusions from 28 men and 28 women (mean age 57 (range 18–90) years) were investigated. The following diagnoses were established: osteoarthritis (31), recent trauma (17), cartilage disorders (three) and infections (five).
Results Significant differences were observed in the absence or presence of infection (mean (range)): pH, 7·3 (7·0–7·5) *versus* 6·9 (6·7–7·0); P_{O_2}, 17·6 (2·8–21·6) *versus* 8·8 (4·3–12·1) kPa; and P_{CO_2}, 6·4 (1·2–12·6) *versus* 13·4 (6·4–17·4) kPa respectively. No differences were observed in pH, P_{O_2} and P_{CO_2} between 17 acute trauma lesions and 34 chronic lesions. The conditions prevailing within knee joints reflect data documented in the abdomen in the absence or presence of infection. Using the threshold values predictive for infection in the abdomen (pH less than 7·1, P_{O_2} less than 6·5 kPa and P_{CO_2} greater than 8 kPa) the following sensitivities and specificities indicating the presence of bacterial knee infection were obtained: pH 100 and 96 per cent; P_{O_2} 60 and 84 per cent; P_{CO_2} 100 and 94 per cent.
Conclusion Data on *in vivo* conditions may be helpful in designing more predictive *in vitro* tests of antimicrobial activity to guide antibiotic treatment of joint infections. In addition, rapid assessment of these pathophysiological variables might be useful for clinical decision making.

Relaparotomy in peritonitis: characterization and outcome of patients with persisting abdominal sepsis

T. Koperna and F. Schulz, *Department of General Surgery, Hospital Lainz, Vienna, Austria*

Background The characteristics and outcome of patients with persisting abdominal sepsis were evaluated.

Methods Some 105 consecutive patients treated from 1986 to 1996, in whom standard surgical treatment of secondary peritonitis failed, were reviewed retrospectively.

Results The mean(s.d.) Acute Physiology And Chronic Health Evaluation (APACHE) II score at the beginning of treatment was 20·7(9·1). Preoperative severe organ failure measured by the GORIS score had a significant impact on survival. A significantly adverse outcome was found in patients older than 70 years ($P = 0·002$), with a duration of illness greater than 24 h ($P = 0·0001$), with a serum albumin level less than 30 g l^{-1} ($P = 0·0001$) and with thrombocytopenia below 60×10^9 per litre ($P = 0·02$). Re-exploration performed more than 48 h after the initial operation resulted in a significantly higher mortality rate (76·5 per cent; $P = 0·0001$). However, the lowest mortality rate (18 per cent) was observed in patients who underwent reoperation on demand within 48 h. The APACHE II scores differed, although not significantly, in all four categories of patients (early and late, planned and relaparotomy on demand). Postoperative organ failure in more than four organ systems with a GORIS score of 9 or more was associated with a mortality rate of 93 per cent. In patients with a GORIS score of 5–8, multiple organ system failure (MOSF) for up to 6 days led to a significantly worse outcome ($P = 0·01$). High-risk patients with diffuse peritonitis require timely and frequent reoperations.

Conclusion These data show that planned and on-demand relaparotomy lead to similar results. However, the decision to perform a relaparotomy on demand must be made within 48 h after the initial operation, at least before MOSF emerges. Better intensive care may help the patient to survive severe MOSF of up to four organ systems. Supporting vital functions over a longer period has been effective in reducing the traditionally high mortality rate in these patients.

Effects of lipopolysaccharide and antibiotics on protein synthesis in muscle and intra-abdominal organs

T. Bark, M. McNurlan and P. Garlick, *Departments of Surgery, Karolinska Hospital, Stockholm, Sweden and SUNY, New York, USA*

Background Intestinal barrier function is suggested to be of increased importance during catabolic states such as trauma and sepsis. Changes in protein synthesis in intra-abdominal tissues during sepsis or after antibiotic therapy are not clear. This study examined changes in protein synthesis rates in muscle and intra-abdominal organs after lipopolysaccharide (LPS) administration and during antibiotic therapy in mice.

Methods In the first part of the study non-fasting Swiss Webster mice received an intraperitoneal injection of LPS or saline. After 230 min a flooding dose of L-[^{2}H5]phenylalanine was injected intravenously. Some 10 min later the animals were killed, blood was collected and tissues were sampled. Protein synthesis rates were measured by the incorporation of injected L-[^{2}H5]phenylalanine into tissue proteins using GCMS. In the second part of the study mice were given either a mixture of streptomycin 2 mg ml^{-1} and bacitracin 2 mg ml^{-1} in their drinking water, or water only together with standard chow. After 3 days a flooding dose of L-[^{2}H5]phenylalanine was injected intravenously and samples were taken in the same way after 10 min.

Results Four hours after LPS, protein synthesis rates (k_s) decreased in all tissues examined (skeletal muscle, spleen, liver, enterocytes, mesenteric lymph nodes (MLNs) and Peyer's patches) by 30–60 per cent ($P < 0·01$). After oral antibiotic treatment k_s decreased in heart, colon and MLNs by 10–20 per cent ($P < 0·01$).

Conclusion After LPS injection, protein synthesis was reduced in all tissues, including intestine and lymphoid tissue. After antibiotic treatment a reduction was seen in heart, colon and MLN protein synthesis, possibly due to disturbed intestinal flora. These effects might be of importance as they may damage intestinal barrier function in septic states.

Peritoneal activation and severity of disease in human peritonitis

W. Sendt, R. Amberg, K. Reinshagen, U. Schoffel, B. U. v. Specht and E. H. Farthmann, *Chirurgische Klinik, Universitat Freiburg, Freiburg, Germany and Institut fur Forensische Medizin, Kantonspital, Basel, Switzerland*

Background The severity of peritonitis can be described clinically by the use of several scoring systems. However, the activation of peritoneal cells has not been included in the grading of peritonitis. This study evaluated the cellular activation of the inflamed human peritoneum and determined possible relations between cellular activation and clinical scores.

Methods In nine patients with diffuse peritonitis, peritoneal specimens were taken at the beginning of intervention. Monocyte–macrophage activity was assessed immunohistochemically using antibodies against macrophage inhibiting factor-related proteins (MRPs) 8 and 14. The antibody clone HAM 56 was used to identify local macrophages. Cellular expression of interleukin (IL) 1 was also measured. All examinations were performed in paraffin sections using the avidin–biotin complex technique. Evaluation of the clinical state was done by using the Mannheim Peritonitis Index (MPI), Peritonitis Index Altona II (PIA II) and Acute Physiology Score (APS). C-reactive protein (CRP) levels were measured before operation in serum.

Results The expression of MRP-8 and MRP-14 showed a focally increased to diffuse dense interstitial staining. Activation corresponded to high CRP values (median 22·0 (range 4·7–42·6) mg dl^{-1}). Resident peritoneal macrophages (HAM 56) showed a relatively slight increase. IL-1 expression was discrete and in some cases not detectable. Activation was independent of MPI (median 30 (range 21–39)), PIA II (+0·57 (−1·64 to +1·79)) and APS (2 (range 1–19)).

Conclusion The pattern of peritoneal inflammatory reactions is relatively uniform and does not correspond to the clinical grading of severity. The surprisingly low expression of IL-1 may reflect downregulation after presumed early increase during the course of peritonitis.

Experimental studies of biliary piperacillin excretion

J. M. Culebras, M. J. Tunon, J. Gonzalez-Galego, C. Barrientos and P. Gonzalez, *Department of Physiology, Pharmacology and Toxicology, University of Leon and Research Unit, Hospital of Leon, Leon, Spain*

Background Piperacillin is a β-lactam antibiotic with broad-spectrum activity against Enterobacteriaceae, enterococci and anaerobes. Its activity, along with high reported biliary levels, has prompted its clinical use in treating biliary infections. A number of organic anions are known to decrease biliary secretion of cholesterol and phospholipid without affecting bile acid secretion. The purpose of the present study was to examine the possible uncoupling effects of different doses of piperacillin on biliary lipid secretion in rats.

Methods Male Wistar rats weighing 250–300 g were injected intravenously with piperacillin at four different doses: 0·3, 1, 2 and 3 nmol per kg body-weight, and bile samples were collected for a total of 2 h. Bile acid, cholesterol and phospholipid concentrations were measured in bile by commercially available enzymatic methods. The bile lithogenic index (i.e. percentage cholesterol saturation) was calculated by the method of Hoffman (1973).

Results Piperacillin administration inhibited bile acid, cholesterol and phospholipid secretion at all doses tested. The cholesterol:bile acid and cholesterol:phospholipid ratios were increased significantly. The phospholipid:bile acid ratio was reduced significantly. The lithogenic index of bile was significantly increased at all doses (+175, +103, +81 and +150 per cent respectively).

Conclusion These data indicate that piperacillin induces a marked reduction in bile acid, cholesterol and phospholipid biliary secretion. This effect gives rise to a greater cholesterol saturation in bile which represents a major factor for cholesterol gallstone formation.

Re-evaluation of empirical antibiotic therapy

I. Iturburu, A. Apecechea, C. Emparan, A. Gomez and J. J. Mendez, *Department of Surgery, Basurto Hospital, Bilbao, Spain and Division of Organ Transplantation, University of Texas, Houston, Texas, USA*

Background Important complications after surgery are surgical infections for which empirical antibiotic therapy is required. To establish precise antibiotic therapy, the microbiological spectrum and sensitivity must be determined. This study examined whether new antibiotics have produced qualitative changes in microbial flora isolated from patients and determined possible modifications in sensitivity.

Methods Some 7414 samples, obtained from 6236 patients operated on by the authors during the past 6 years, were analysed retrospectively. The frequency of isolation of the most common organisms was determined and changes in sensitivity after different antibiotics were evaluated.

Results A significant global change was found ($P = 0{\cdot}0008$) in surgical bacteriology responsible for infection, with a significant reduction ($P = 0{\cdot}006$) in *Staphylococcus aureus* and an increase in *Staphylococcus epidermidis* ($P = 0{\cdot}026$). An increase in the isolation of fungi was also observed ($P = 0{\cdot}00006$). Modifications in the incidence of *Escherichia coli*, *Pseudomonas aeruginosa* and *Streptococcus faecalis* were not confirmed. Changes in sensitivity were not observed, with the exception of *P. aeruginosa*, which showed a decrease in sensitivity to piperacillin ($P = 0{\cdot}0033$), although a sensitivity of 100 per cent was associated with tazobactam, and sensitivity to ceftazidime and amikacin was maintained at 100 per cent. A decrease in sensitivity to cefotaxime of between 75 and 39 per cent ($P = 0{\cdot}014$) was observed and to gentamicin of between 100 and 76 per cent, while sensitivity to tobramycin was maintained at over 90 per cent. *P. aeruginosa* presented over 90 per cent resistance to amoxycillin–clavulanic acid, which is a widely used antibiotic in these wards. Finally, non-urinary *E. coli* showed changes in sensitivity to cephazolin ($P = 0{\cdot}000001$).

Conclusion A decrease in *S. aureus*, as responsible for surgical infections, has occurred with a progressive increase in *S. epidermidis* and fungi. With the exception of *P. aeruginosa* and non-urinary *E. coli*, no changes in sensitivity were observed. It is useful periodically to evaluate the frequency of isolated organisms and sensitivity to establish a typical flora in each department and to evaluate the need to modify antibiotic therapy.

Low molecular weight heparin and unfractionated heparin in thrombosis prophylaxis after major surgical intervention: update of previous meta-analyses

Sir

I read with interest the article by Koch *et al.* (*Br J Surg* 1997; **84**: 750–9) in which unfractionated heparin was compared with low molecular weight heparin (LMWH) in the prevention of postoperative deep vein thrombosis (DVT).

In a subgroup analysis the authors conclude that in general surgery a high dose of LMWH is not more effective than a low dose and that the low dose is a more promising concept. The authors state that the results of a large clinical trial would be more reliable than the results from a meta-analysis; there is such a study[1] that the authors may have missed. This is difficult to understand as data were collected from pharmaceutical companies and Medline until March 1996. The sample size calculation in this prospective double-blind randomized multicentre study was made to allow an analysis of the prophylactic effect and safety in patients undergoing elective surgery for abdominal malignancy. The results (frequency given as percentage) in the 1303 patients was as follows:

	Dose of Dalteparin		95 per cent confidence interval of differences
	2500 units	5000 units	
DVT* (intention to treat) ($n = 1303$)	14·9	8·5	2·1 to 8·9
DVT* (correct prophylaxis) ($n = 1154$)	15·1	8·8	2·1 to 9·4
Haemorrhagic complication	3·6	4·6	−2·8 to 1·4

*Deep vein thrombosis (DVT) diagnosed by fibrinogen uptake test

Meta-analysis is a valuable scientific instrument with advantages and disadvantages, but large properly performed controlled trials are the gold standard to evaluate the efficacy of clinical interventions. This view is strongly supported by recent data from a comparison between results in meta-analysis and randomized controlled trials on the same topic[2]. The dose comparison made by Koch *et al.* shows that these are important factors influencing the results of clinical studies but not taken into account in a meta-analysis. In this case such factors could be differences in patient population and time of first dose.

Author's reply

Sir

We welcome the comment by Dr Bergqvist and the opportunity to reply. Our meta-analysis was intended to resolve the question of whether LMWH can replace unfractionated heparin (UFH) under certain circumstances and therefore did not include the study of Bergqvist *et al.*[1]. This study investigates another question (randomized and double-blind comparison to assess a dose–response effect). This has correctly been termed the gold standard for treatment comparisons and our results can, at best, add some additional evidence. Dr Bergqvist's conclusion from our meta-analysis that low-dose LMWH is superior to high-dose LMWH is based on an indirect comparison which, in our opinion, exceeds what can be achieved in a publication based meta-analysis[2].

We agree that (even for the comparison of LMWH and UFH) many questions remain unresolved[3]. Treatment effects may differ in high- and low-risk patients (as is indicated by Dr Bergqvist's results), the role of mechanical methods in thrombosis prophylaxis needs investigation and additional information on commencement of treatment before and after surgery is necessary.

Effect of a no-conversion policy on patient outcome following laparoscopic cholecystectomy

Sir

We read with interest the paper by Wallace and O'Dwyer (*Br J Surg* 1997; **84**: 1680–2) but were surprised at its main conclusions. The authors state that one of the potential drawbacks of laparoscopic cholecystectomy is lack of experience with the open procedure. Advocacy of a no-conversion policy will further restrict an already diminishing experience with open cholecystectomy with implications for surgical trainees.

We believe it to be unwise to suggest that surgeons should not convert to an open procedure. Those with less experience than Mr O'Dwyer might be tempted not to convert with potentially significant complications. The authors compared an early with a more recent experience and outlined the reasons for conversion in the first 127 procedures. No information is given concerning the number of patients in the more recent series with previous abdominal surgery, intraoperative difficulties in identifying biliary anatomy or haemorrhage. Are these groups strictly comparable?

Between July 1990 and December 1997, 896 laparoscopic cholecystectomies were performed in our unit, of which 75 were converted to an open procedure (8·4 per cent). Indications for conversion included anatomical uncertainty or adhesions from previous surgery ($n = 48$), empyema ($n = 14$), bleeding ($n = 4$) and technical problems ($n = 4$). We do not believe that it is always possible to be certain of biliary anatomy during laparoscopy. Conversion should be undertaken in this circumstance, as the risks of open cholecystectomy are less than those associated with laparoscopic bile duct injury. In our experience learning curves or better laparoscopic instruments do not diminish the need for open cholecystectomy in a small percentage of patients. These patients, by the nature of their disease, demand even more experienced surgical technique.

Author's reply

Sir
We are grateful to Mr Barry and colleagues for their comments but they appear to confuse one of our introductory statements, that one of the potential drawbacks of laparoscopic cholecystectomy is lack of experience with open cholecystectomy, with our only conclusion that a no-conversion policy can be adopted for laparoscopic cholecystectomy without adversely affecting patient outcome. There was no difference between the patients in both groups in our study with respect to previous abdominal surgery, severity of disease etc. We know of no published series where conversion rates have not diminished with experience and it will not always be possible to demonstrate the anatomy at open cholecystectomy and the risk of serious bile duct injury may be no less than that at laparoscopic cholecystectomy. In the small percentage of patients where laparoscopic cholecystectomy is not feasible, and this should be 1–2 per cent of patients rather than the 8 per cent suggested by Barry *et al.*, we believe cholecystectomy, with complete stone removal, may be the safest procedure.

Magnetic resonance imaging in evaluation of the common bile duct

Sir
The clinical role of magnetic resonance cholangiopancreatography (MRCP) and how the algorithm proposed by Musella *et al.* (*Br J Surg* 1998; **85**: 16–19) may fit into routine clinical practice remains unclear. The main criticism of MRCP, when compared with endoscopic retrograde cholangiopancreatography (ERCP), has been that no therapeutic option can be offered when diagnostic information is obtained[1]. The authors suggest routine MRCP for patients with symptomatic common bile duct (CBD) involvement (jaundice, evident biochemical abnormality and dilated ducts on ultrasonography). ERCP is usually necessary in many of these patients as a therapeutic procedure either for sphincterotomy and stone removal or for temporary or permanent stenting in the event of benign or malignant stricture. In their series nine of 11 patients in this category underwent subsequent ERCP and sphincterotomy. MRCP may only add further to the cost of diagnostic investigation in these patients without providing any additional benefit or information.

The potential clinical application of MRCP may be in the following circumstances: (1) patients who require purely diagnostic ERCP examination; (2) after unsuccessful ERCP; (3) when technical difficulties of ERCP can be anticipated; and (4) for evaluation of the biliary tree in patients with mild biochemical or ultrasonographic signs of CBD involvement before laparoscopic cholecystectomy[2].

Author's reply

Sir
The main criticism you level against MRCP in patients symptomatic for involvement is that it adds costs without providing any additional information. Allow us to disagree with you for the following reasons.

First, the most frequent causes of 'surgical' jaundice remain CBD stones or periampullary and pancreatic head carcinoma. The purpose of the study on symptomatic patients was to demonstrate that MRCP and ERCP in such patients had the same efficacy. Many authors[1,2] do not suggest diagnostic ERCP in symptomatic patients when a periampullary or pancreatic malignancy is suspected. In such patients an assessment of mass extension and resectability by the combined use of MRCP and helical computed tomography is to be preferred. ERCP will be useful for non-resectable lesions when a stenting procedure is required. On the other hand if stones are seen at MRCP, we prefer to drain the CBD by endoscopic sphincterotomy, as suggested in the algorithm. Others[3], who want to preserve sphincter function, will attend to choledocholithiasis at the time of laparoscopic cholecystectomy. ERCP is not the only therapeutic option to treat CBD stones; it is an invasive diagnostic approach that should be performed only when an operative procedure (sphincterotomy, stenting) is required on the basis of a previous non-invasive evaluation.

Second, the same authors[4] cited by Mr Sudhindran, in a newer series, have enlarged their indication to perform MRCP. It may decrease significantly the need for purely diagnostic ERCP, and is therefore recommended in the routine diagnosis of biliary tract disease.

Prognostic factors in a series of 297 patients with gastric adenocarcinoma undergoing surgical resection

Sir

I was interested to read the paper by Sánchez-Bueno *et al.* (*Br J Surg* 1998; **85**: 255–60) describing prognostic factors in patients who had undergone surgical resection for gastric carcinoma. Clinical, treatment-related and anatomicopathological variables were analysed but no mention was made of variables relating to tumour biology. Recent reports have described components of the plasminogen activating system as new factors that are also associated with poor prognosis.

Urokinase plasminogen activator and its inhibitor PAI-1, determined by semiquantitative immunohistochemistry[1,2] or by enzyme-linked immunoassay[3–5], were shown to be independent prognostic parameters for short survival, particularly in patients with diffuse-type tumours by the Laurén classification. Heiss *et al.*[6] showed that the expression of the urokinase plasminogen activator receptor on disseminated tumour cells in bone marrow aspirates taken at the time of surgery from patients with gastric carcinoma predicts early relapse and is an independent prognostic variable.

The urokinase plasminogen activator system is thought to have an important role in the cellular mechanisms that result in invasion and metastasis[7]. It is interesting to note that in the multivariate analysis performed by the authors two of the four independent variables, penetration depth of gastric wall and lymph node involvement, are the consequences of these processes. Measurement of components of this system in patients with gastric carcinoma provides additional prognostic information which may be useful in planning treatment.

Pilonidal sinus: experience with the Karydakis flap

Sir

I thank Dr Kitchen (*Br J Surg* 1996; **83**: 1452–5) and Schoeller *et al.*[1] for their contributions to pilonidal disease. Dr Kitchen's symmetrical flap excision is an important refinement. Both authors properly emphasize the importance of creating a shallow cleft and placing the final suture lines away from a deep midline.

Which operation is simplest? Muscle transfers are unnecessary as the authors point out. Shifting of fascia and fat is also unnecessary. The goal is to reshape dermis and epidermis and, therefore, skin alone needs to be moved[2]. Experience shows that fat falls into place and heals beneath intact skin.

A chronic abscess wall is a victim to be protected. Its cells are striving to heal in a choking cloud of anaerobic bacteria which flood in from their breeding place in the airless cleft. The embattled fat is not a villain to be cut away as the 'total excision to periosteum' as conventional texts instruct. Such instructions are based on a faulty concept of the deformed tissues as generator, not sufferer, of disease. Freed of the noxious infusion from a damp cleft, deep tissues will always heal[3]. Total excision hospitalized 79 000 servicemen for an average of 55 days in World War II and was abandoned.

Shallow clefts and ventilated suture lines solve every pilonidal problem unresponsive to conservative treatment if excision of the rare epithelial tube is included. In the search for the simplest effective operation, shifting skin alone as a day-surgery procedure has much to recommend it.

Topical glyceryl trinitrate cream for anal fissure

Sir

Glyceryl trinitrate (GTN) cream has recently been advocated as an effective treatment for anal fissure[1]. Apart from headache it appears to produce few complications but two recent patients highlight the pitfalls of its widespread indiscriminate use.

Patient 1. A 43-year-old man presented to his general practitioner (GP) with a 3-month history of perianal pain aggravated by defaecation with increased mucus production and traces of bright red blood on defaecation. Intense sphincteric spasm prevented digital rectal examination. He was given topical 0·2 per cent GTN cream for 1 month. Despite slight improvement significant symptoms persisted and he was referred to a colorectal surgeon. Intense sphincteric spasm made examination impossible. Examination under anaesthesia revealed a low rectal carcinoma. He received preoperative radiotherapy followed by a low anterior resection with a colonic J pouch.

Patient 2. A 49-year-old man presented to his GP with fresh rectal bleeding and pain on defaecation. He had anal spasm and an oedematous skin tag. GTN cream (0·2 per cent) was applied for 2 months with no success. When referred to the surgical department a squamous cell carcinoma of the anal canal was found which was treated by chemoradiation.

Edwards *et al.*[2] demonstrated that patients with anal carcinoma are often given a benign diagnosis before the true nature of the disease is established and others have suggested that this may adversely affect prognosis[3]. These patients illustrate the importance of excluding more serious conditions before relying on topical GTN. The option of treating anal fissure without operation does not reduce the need for full examination, if necessary under anaesthesia.

Long-term oral administration of branched chain amino acids after curative resection of hepatocellular carcinoma: a prospective randomized trial

Sir
I read with interest the report from the San-In Group of Liver Surgery promoting the benefits of branched chain amino acids (BCAAs) after liver resection for hepatocellular carcinoma (*Br J Surg* 1997; **84**: 1525–31). The authors suggest that prolonged oral intake of a proprietary feeding solution rich in BCAAs (Aminoleban EN, Otsuka Pharmaceutical Company, Tokyo, Japan) may be of benefit in improving clinical and biochemical recovery after hepatectomy in patients with underlying liver disease. Unfortunately, this interpretation is not supported by the data. The study design is seriously flawed due to the lack of a control group with supervised intake of an isonitrogenous, isocaloric feeding supplement. While the treatment group was given 100 g of the test formulation per day (containing 27 g protein, 62 g dextrin and 7 g rice oil, and providing 420 kcal) in addition to normal diet for 1 year, the control group 'ate their usual meals'.

It is widely accepted that in patients with chronic liver disease impaired dietary intake is one of the principal causes of nutritional deficiency (although absorptive and metabolic derangements may also contribute)[1]. Furthermore, the role of BCAA feeding formulas in this group of patients is far from clear, with studies providing conflicting results and demonstrating uncertain benefit[2]. There is evidence that conventional protein and casein preparations produce comparable results to BCAA solutions when given over prolonged periods[3]. I suggest that the benefit demonstrated in the study by the San-In group can be explained largely by the overall effect of improved protein calorie intake, rather than any specific effect mediated by BCAAs. In this regard, the recent clinical guidelines issued by the American Society for Parenteral and Enteral Nutrition recommend that BCAA-enriched formulas be reserved for patients with established encephalopathy in whom standard medical care has failed and adequate protein intake cannot otherwise be tolerated[4]. While the search for therapies to improve recovery (and liver regeneration) after hepatectomy in patients with cirrhosis continues, it is important that future attempts to evaluate specific nutritional strategies should have an appropriate isonitrogenous, isocaloric control arm. Improperly controlled studies simply add further confusion to a clinical problem replete with unproven (feeding) solutions.

Anatomical variants during axillary dissection

Sir
We enjoyed the informative article by Kutiyanawala *et al.* (*Br J Surg* 1998; **85**: 393–4) discussing the anatomical variants within the axilla. They describe six instances of an abnormal band of muscle and/or tendon stretching across the axilla and we feel that this issue needs clarification.

The most common anatomical muscular variant is the 'axillary arch of Langer' (Langer'ser Achselbogen), first described in 1846 and also called the 'axillopectoral muscle'[1]. It arises from the anterior axillary portion of the *latissimus dorsi*, runs across the neurovascular bundle and is inserted into the posterior aspect of the trilaminar tendon of the pectoralis major close to the humerus. Its innervation is via branches of the nerve to pectoralis minor. The muscle is rendered taut by elevation and abduction of the arm and is said to be present in 0·25–7 per cent of the population[2]. In our experience the incidence is 0·8 per cent (17 patients in approximately 2000 axillary dissections).

There have been descriptions of other muscular and tendinous arches in the axilla. They may arise from the *latissimus dorsi*, pectoralis major, thoracic fascia, external oblique aponeurosis or ribs and costal cartilages. We have previously encountered a muscle arising as separate bellies from the lateral aspect of *latissimus dorsi* and serratus anterior, before joining to insert into the humerus[3]. Their insertions are commonly into the trilaminar pectoral tendon, upper humerus or coracoid process. Occasionally, they may insert into the fascia of the arm, extend into flexor muscles of the arm or extend down as the 'chondroepitrochlearis muscle' as far as the medial epicondyle[4]. The innervation of these muscles is frequently from the medial pectoral nerve, thus indicating the embryological origin from the pectoral muscle mass[2]. Others may be supplied by the intercostobrachial, the medial cutaneous nerves of the arm, or the thoracodorsal nerve. They may also be found in association with other muscular abnormalities of the pectoral girdle, for example, the rectus sternalis muscle. It is suggested that these muscular arches of the axilla may be rudimentary phylogenetic remnants of the panniculus carnosus which is well developed in some lower mammalian species, particularly cats[5].

As Kutiyanawala *et al.* have stated the thoracodorsal neurovascular bundle is important for breast reconstruction using the *latissimus dorsi* myocutaneous flap, and if the arch is not divided it may result in an entrapment syndrome and flap ischaemia.

Book reviews

Vascular Surgery. A Comprehensive Review. 5th ed.

W. S. Moore (ed.). 285 × 219 mm. Pp. 903. Illustrated. 1998. Philadelphia: Pennsylvania: WB Saunders. Price not supplied.

Some of the most distinguished American vascular surgeons have contributed to this book and important chapters on endovascular techniques have been added. In the preface of the first edition the authors stated that 'the intention of this textbook is to provide a comprehensive review of vascular surgery together with medical and basic science disciplines'. There can be no doubt that the authors have succeeded and, in my opinion, the present book is one of the most important reference works in vascular surgery. The book starts with an interesting historical review followed by valuable chapters on embryology, anatomy, physiology and pharmacology of the arterial wall. There is an excellent chapter on surgical exposures giving detailed and concise information. Haemostasis and thrombosis are well covered and information is given about drug interaction and screening in patients suspected of having coagulopathy. The chapters on atherosclerosis, including haemodynamic factors, are of excellent quality and the same can be said about the description of non-atherosclerotic vascular disease. Good practical advice is given about the treatment of diabetic patients before and after surgery. It is, however, stated that measurement of ankle blood pressure is useful in diabetics. This is in contrast to the general view of preferring toe pressure measurements in this particular group of patients. The chapters on haemodynamics and the vascular laboratory, including information about duplex scanning, are excellent. The technique of measurement of arterial blood pressure of the toe as well as direct measurement of venous pressure might have been included in this chapter. Angiography and interventional radiology are well presented but intentional subintimal angioplasty is not described. The various endovascular techniques including aneurysm repair are up to date and endovascular management of traumatic vessel injuries is reviewed. Endovascular treatment of thoracic aortic aneurysms is not included. The theoretical background, contraindications and practical aspects of thromobolytic therapy is well covered in chapter 20. Regarding evaluation of cardiac risk in patients with vascular diseases I would have preferred the technique of dobutamine stress echocardiography to be included.

Atherosclerotic thoracoabdominal aneurysms are mentioned together with aortic dissections. Perhaps a separate chapter on dissection would have been advantageous as many of these patients are taken care of by vascular surgeons. All aspects of abdominal aortic aneurysm are well presented but more illustrations in this chapter would have made it easier to read. Balloon angioplasty and stenting are not given much attention in the chapter on aortoiliac occlusive disease although this may now be the first option when treating these patients. Infrainguinal occlusive disease is covered fully and sound advice regarding both conservative measures and operative treatment is given. The chapters also include tables of operative results giving the reader the opportunity to compare with his/her own results. Percutaneous transluminal renal angioplasty (PTRA) and stenting are not given much attention in the chapter on renovascular hypertension, probably because stents are not yet approved for this use in the USA. In most European centres PTRA is now the first option in patients with renal artery stenosis whereas open revascularization is used when specially indicated.

Extracranial cerebrovascular disease is extremely well presented by the editor perhaps reflecting his special interest in this field. Supra-aortic vessel disease is included although balloon angioplasty is not given much attention. The chapter covering haemodialysis is excellent and new endovascular approaches are discussed. Complications that might follow arterial surgery are described thoroughly. However, the possibility of using obturator bypass for problems with localized graft infection in the groin is not mentioned. Venous problems including thromboembolic disease and varicose veins are presented in a clear and concise way. In this chapter, a couple of schematic illustrations of the haemodynamics of venous insufficiency and how to separate deep from superficial venous insufficiency would have been useful. Although much attention is given to the problem of selecting the level of amputation, one is left with the impression that the problem has not yet been solved. In general, I would have changed some of the illustrations from operative situations with schematic illustrations or perhaps supplemented them, examples are 36-1c and 36-2c.

Regardless of these insignificant objections, one is left with the impression that this is an excellent review which can be recommended to those with an interest in vascular surgery, including registrar trainees. The references are numerous and of good quality. The review questions are excellent for self-evaluation following each chapter. The quality of the paper is good and most illustrations are of excellent quality. This outstanding book is recommended as one of the reference works that should be available in departments of general and vascular surgery.

Cybersurgery. Advanced Technologies for Surgical Practice

R. M. Satava (ed.). 155 × 235 mm. Pp. 201. Illustrated. 1998. New York: Wiley-Liss. £55.

This is an intriguing book with a catchy title that is well worth a read. It describes a variety of advanced engineering techniques that are likely to change the nature of surgical procedures as we know them today. Virtual reality, telepresence surgery, computer-aided surgery and microelectromechanical devices are all covered. I was intrigued by the term 'medical avatar' which is a full volumetric representation of the patient that can be used to plan and perform surgery.

In contrast to the futuristic subject the book is irritatingly old-fashioned in format with poor-quality black and white photographs and a few colour plates in the centre. Although the series title is *Protocols in General Surgery* this is essentially a transient book. I read most of it on a train journey and, by coincidence, my daily newspaper had some of the same material in it. It is quite clear that surgical methods are going to change dramatically and this volume offers an insight into the sort of changes we may see surprisingly soon.

J. Bancewicz

Long-Term Results of Arterial Interventions. European Vascular Course – 1997 Volume

A. Branchereau and M. Jacobs (eds). 278 × 217 mm. Pp. 328. Illustrated. 1997. Armonk: Futura Publishing. US$95.

The book of the *Annual Meeting of the European Vascular Course* is published in English and French, the French originators now inviting English-speaking pundits. Of the 117 contributors, 56 are French and the others generally well-known names in the English literature who are responding to a familiar brief. The exchange of ideas provides insight into Gallic flair for intervention, Anglo-Saxon scepticism, and the mixed tenses and 'franglais' typography provide some amusement. The book has variegated style, modest illustrations and insufficient editorial discipline. Its aims are to disseminate expertise across cultural frontiers. However, while some important results are reported, for example the late complications of aortic grafts, many authors tell us about their large series without stating their criteria for selection or management. A wealth of surgical expertise is thereby squandered in unregulated practice and we finish up none the wiser. We learn that, in more than 3000 carotid procedures, a shunt has been used since 1989 for contralateral occlusion but there are no data to show why (despite 100 references) and we have no guidance on the quality of evidence from some of the acknowledged experts. Carotid bypasses are reported but only patency analysed, and a series of nearly 100 allografts, while stimulating, does not satisfy.

Some chapters undoubtedly have interest and value. Peter Bell gives a clear and well illustrated account with only 18 references, all in English. Some chapters provide an intriguing insight into differences in the clinical situation; for example the Marseilles aortic aneurysm patients, 431 elective but only 26 emergencies. Some authors report experience which does not seem to apply elsewhere. For instance, how is it that in Rouen small vein grafts work better if reversed below the knee? The editors are to be congratulated on their enterprise in promoting the 'entente cordiale' but there is more to do. We have shared our questions and should share the unavoidable responsibility of providing answers. Neither patients nor governments are impressed with mere technique or experience: they want real results.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** To avoid subsequent embarrassment, please submit with your manuscript copies of any other papers, either published, in press, or submitted for consideration elsewhere, which relate to the same subject. It is essential that you submit any other publications or submissions using the same data set to the Editors to allow assessment of any potential overlap with the submission to the Journal. Indicate on the title page whether the paper is based on a previous communication to a society or other meeting. Articles and their illustrations become the property of the Journal unless rights are reserved before publication.

Send four copies of original articles and other editorial matter to: The Editor, *The British Journal of Surgery*, Blackwell Science Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 0171 404 1831. Facsimile: 0171 404 1927. Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. State in the covering letter whether an abstract of the work has been published and give an appropriate reference on the title page. Disclose in the covering letter any potential or actual personal, political or financial interest you may have in the material, information or techniques described in the paper. The decision to publish or withhold such information will be made by the Editors. Acknowledge all sources of financial support for the work. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents. The Journal accepts the criteria for authorship proposed in the *British Medical Journal* (*BMJ* 1994; **308**: 39–42). When a paper has many authors (i.e. more than six), you may be asked to justify the inclusion of all names listed. Results of multicentre studies should be reported under the name of the organizing study group. Methods of recognizing contributors have been proposed (*Lancet* 1995; **345**: 668).

Disks

Following final approval of articles, you will be asked to submit the accepted version on disk. These should be IBM-compatible. An accurate hard copy must accompany each disk, together with details of the type of computer used, software, and disk system if known. **Do not justify**. Please send us digital versions of your figures. Ideally, these should be sent in native format or WMF if created in Windows. Files saved as PS, EPS, GIF and TIF may also be used, but please note that it may not be possible to modify them. Avoid using tints if possible; if they are essential, try to make them coarse. Further details can be obtained from the publisher. Disks will not be returned to authors.

Rejected manuscripts and illustrations will not normally be returned.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethics committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs that might identify an individual. Submit evidence of such consent with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts, which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *New England Journal of Medicine* 1997; **336**: 309–15, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1.00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, state in parentheses the brief name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal believes that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript must have a 200-word structured abstract. Lengthy manuscripts are likely to be returned for shortening. The discussion in particular should be clear and concise and should be limited to matters arising directly from the results. Avoid discursive speculation. **Randomized clinical trials** should be clearly identified as such in the title and abstract.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles which are 600–900 words in length and address controversial topics of current interest. They should be supported by no more than ten key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Correspondence

The Editors welcome topical correspondence relating to articles published in the Journal. Letters should not exceed 250 words and should be typed double-spaced.

Typescripts

Manuscripts must be clearly reproduced with adequate space for editorial notes. **Type or print the text on one side of sheets of A4 paper (210 × 297 mm) with double spacing and 4-cm margins. Manuscripts that do not conform to these requirements will be returned to you for recasting.** Begin each section (abstract, introduction, patients and methods, results, and discussion) on a new page.

Title page

On the title page give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone, facsimile and e-mail numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, review etc.).

Abstract

This should be not more than 200 words on the second page of the manuscript and be presented in a structured format. **Background:** state why the study was done, and its main aim; **Method:** describe patients, laboratory material and other methods used. Clearly identify the nature of the study: randomized controlled trial, retrospective review, experimental study, etc. **Results:** state the main findings of the study; include important numerical values. **Conclusion:** state the main conclusion drawn from the results. Controversial or unexpected observations may be highlighted, but keep this section brief. Write the abstract in clear prose.

Tables and illustrations

Submit three copies of all illustrations and tables. Type each table on a separate page with an appropriate brief title. Line drawings are acceptable as clear black on white graphics, computer printout or photocopies. Submit radiographs, photomicrographs, etc unmounted in the form of glossy prints, original transparencies or negatives. If you include photocopies, they should be of sufficient quality to enable the Journal's referees to judge their content and value. Label each illustration on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); indicate the top of the illustration. Include a measure of magnification of photomicrographs. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Include explanations of symbols and shading in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. Include in the legends to illustrations and the footnotes to tables brief but comprehensive explanations of all the information presented. Look at recent issues of the Journal for examples of accepted layout. If a table or an illustration has been reproduced from a published work give the original source in full. Obtain permission to use published work from the original author and the publisher before submission.

Abbreviations

Use abbreviations sparingly. Terms that are mentioned frequently may be abbreviated but only if this does not impair comprehension by the reader. Use abbreviations consistently throughout the text and clearly define each one on first use.

Numbers and units

Use the decimal point, not a comma, e.g. 5·7. Use a space and not a comma after thousands and multiples thereof, e.g. 10 000. Use SI units (International System of Units) except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, give the actual values and units, with SI equivalents inserted in parentheses at appropriate points.

Statistics

For detailed guidance on the handling of statistical material, consult *Br J Surg* 1991; **78**: 782–4. In evaluating a manuscript the Editors and statistical referees will consider the design of the study, the presentation and analysis of data and the interpretation of results.

Design

Set out clearly the objectives of the study, identify the primary and secondary hypotheses, and the chosen end-points, and explain the rationale for the choice of sample size. Investigators embarking on randomized controlled studies may wish to consider the CONSORT statement (*JAMA* 1996; **276**: 637–9).

Presentation

Whenever possible use graphical presentation to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. Do not use the '±' symbol; these statistics should be presented in parentheses after the mean value.

Analysis

Clearly describe which methods were used for which analyses; any methods not in common usage should be supported by references. Report results of statistical tests by stating the value of the test statistic, the number of degrees of freedom and the *P* value, e.g. '$t = 1 \cdot 34$, 16 d.f., $P = 0 \cdot 20$'.

Actual *P* values should be reported to two decimal places, especially when the result is not significant, rather than stating 'not significant'. Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, *P* values.

Interpretation

Do not confuse statistical significance with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Beware of placing undue emphasis on secondary analyses, especially when they are suggested by an inspection of the data.

References

Type the references with double spacing in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged. Reference to unpublished communications will not be accepted. Cite personal communications in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, number the references consecutively by superscript: ^{1} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation is quoted); year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer, 1981: 123–63.

Aims and scope

The *British Journal of Surgery* is the premier general surgical journal in Europe and one of the top surgical periodicals in the world. Its international readership is reflected in the prestigious International Editorial Board, supported by a panel of over 900 reviewers worldwide.

The *British Journal of Surgery* features the very best in clinical and laboratory-based research on all aspects of general surgery and related topics. Developing areas such as minimally invasive therapy and interventional radiology are strongly represented.

The inclusion of Leading Articles, Reviews, Original Articles, and articles 'For Debate' means that the *British Journal of Surgery* offers an appropriate format for any length or type of submission; in addition, there are abstracts from key meetings, correspondence, book reviews, conference dates and regular digests by the European Editor of the contents of other major journals. The *British Journal of Surgery* will be of interest not only to general surgeons, but also to specialty surgeons and those working in related fields.

Subscriptions

The *British Journal of Surgery* is published monthly (one volume per annum) in 1998. Subscription prices for 1998 are:

	EUROPE	OVERSEAS	NORTH AMERICA
Institutional	£122.00	£137.00	$227.50
Individual	£79.00	£90.00	$149.50

Subscribers in Canada must add 7% to the subscription price to allow for GST. Subscribers in Europe must quote their VAT registration number or state that they are not registered. Subscribers in the following countries who are not VAT-registered must add VAT at the appropriate rate:

Belgium (6% TVA/BTW)
France (2.1% TVA)
Germany (7% MWST)
Spain (4% IVA)
The Netherlands (6% BTW)

Orders for current subscriptions and back issues should be sent to Blackwell Science Ltd, Journal Subscriptions, PO Box 88, Oxford OX2 0NE, UK. Tel: +44 1865 206180 or 206038; Fax: +44 1865 206219; e-mail: journals.cs@blacksci.co.uk

Despatch

The *British Journal of Surgery* is despatched within the UK by second class post, within Europe by air mail, and to other continents by various forms of air-speeded delivery, to the USA by air freight for forwarding by second class post*, to India by air freight for guaranteed local delivery, and to all other countries by accelerated surface post. Add to the cost of a regular subscription £24.00/$36.00 for air mail delivery outside Europe.

Business correspondence

All other business correspondence, including orders for offprints (offprints@blacksci.co.uk) and advertising space (advert@blacksci.co.uk) should be addressed to:

The *British Journal of Surgery*, Blackwell Science Ltd, Osney Mead, Oxford OX2 0EL, UK. (Tel: +44 1865 206206; Fax: +44 1865 721205).

Eurosurgery 98

This supplement contains the abstracts of papers to be presented during the Eurosurgery 98 Meeting in Budapest. The quality of the material to be presented is self-evident from these pages. The abstract selection has been, as usual, rigorous and thorough. The *British Journal of Surgery* is pleased to produce this abstract book as a supplement, as a sign of our continuing association with Eurosurgery.

The Journal wishes every success to the meeting of Eurosurgery 98. The Editors of this supplement hope that all participants have an enjoyable and stimulating meeting.

Adjuvant chemotherapy using fluoro-uracil, epirubicine and cisplatine (FEP) after curative resection of gastric carcinoma

J.L. Bouillot, K. Aouad, D. Heudes, C. Boiron, F. Aimé, S. Oudard, L. Chauvenet, E. Pujade Lauraine, J. Fourmestraux, J.H. Alexandre and J.P. Béthoux *Departments of Surgery and Biostatistics, Hôpitaux Broussais et Hôtel Dieu, 1, Place du Parvis Notre Dame, 75004 Paris, France*

Aim: The benefit of adjuvant chemotherapy (AC) after curative resection for gastric carcinoma is still debated. This prospective phase II trial analysed our experience with adjuvant chemotherapy after gastric resection for adenocarcinoma.
Patients and methods: Eighty-seven patients with gastric adenocarcinoma underwent gastrectomy as primary surgical management between January 1990 and December 1995 (52 males and 35 females, mean age: 64·3±13·2 years). There were 20 palliative resections and 67 curative ones (37 distal gastrectomy and 50 total gastrectomy). A chemotherapy of FEP (four courses of fluoro-uracil, epirubicin, cysplatin) was postoperatively proposed after curative resection for 25 patients <75 years, in good status (OMS <2) with a histopathological examination showing nodal invasion.
Results: The types of gastrectomy performed were 18 D 1, 41 D 2, 8 D 3, with the mean number of lymph nodes removed 13·8. The staging of tumours, according to the pTNM classification, in the AC group was stage I: two patients; stage II: two patients; stage III: 19 patients; stage IV: two patients vs 14 patients stage I, 11 patients stage II, 16 patients stage III, one patient stage IV in the non-AC group. Chemotherapy was globally well tolerated. It had to be stopped in one case, the dose reduced in three cases, and was accompanied with digestive troubles in six cases. The median survival for the 67 patients with curative resection was 38 months (ED 14·7). It was 38·1 months (ED 12·8) in the subgroup AC vs 51·6 months (ED 23·9) in the absence of AC ($P<0·0001$). This better prognosis concerning the group without AC was due to the large number of patients (19/42) without nodal invasion. In the subgroup of stage III patients, the median survival was 38·1 months (ED 10·5) with AC vs 17·5 months (ED 11·7) without AC ($P=0·19$).
Conclusion: Adjuvant chemotherapy of FEP type seemed to improve survival after curative gastric carcinoma resection, especially for stage III patients with nodal invasion. Its benefits need to be evaluated in large prospective randomized trials.

Prognostic value of p53 protein in colorectal carcinoma

M. Diez, A. Gutiérrez, A. López, P. Martínez, P. Hernandez, A. Martín, J.M. Mugüerza, R. Villeta, A. Ruiz, F. Noguerales and J. Granell *Cirugía General, Hospital Universitario Príncipe de Asturias, 28805 Madrid, Spain*

Aim: To analyse the prognostic value of a set of pathological variables after curative resections for large bowel adenocarcinoma and to test a prognostic score derived from factors with independent predictive effect.
Material and methods: The study is based on data from 292 consecutive unselected patients (B–C Astler–Coller stages). Histopathological features were evaluated prospectively on resected primary tumours. Relationship between factors and risk of recurrence was assessed by a Cox's proportional regression analysis.
Results: Four variables retained independent prognostic significance with respect to the risk of tumour recurrence: extent of bowel wall invasion (intramural vs extramural), peritumoral lymphocytic infiltration (present vs absent), number of positive nodes (none vs one to four vs more than four) vascular invasion (present vs absent). A prognostic score was defined with those four variables. Each variable was weighted according to the regression coefficient attained. This system revealed four prognostic groups. Group I (scores 0·5–1) included 42 (14 per cent) patients, Group II (scores 1·5–2) included 103 (35 per cent), Group III (scores 2·5–3) 127 (43 per cent), and Group IV (scores 3·5–4) 20 (7 per cent). Tumour recurrence was detected in two (5 per cent) patients of Group I, 16 (15 per cent) in Group II, 44 (35 per cent) in Group III, and 13 (65 per cent) in Group IV ($P<0·001$). Five-year disease-free survival was 95 per cent in Group I, 60 per cent in II; 46 per cent in III; and 24·4 per cent in IV ($P<0·01$).
Conclusion: A prognostic score based in the evaluation of four histopathological parameters concerning the tumour phenotype, enables the identification of subgroups of patients with different risk of relapse after curative resection of colorectal adenocarcinoma.

Prognosis of surgical treatment of gastric cancer according to extend lymphadenectomy

F. Docobo, M. Fernandez, M. Tamayo, M. Dovale, M. Lozano, J. Torres and A. Garcia Perla *St. Camilo Jose Cela, Manzana 1-bloque 8-3°A 41018 Seville, Spain*

Aim: The worldwide decrease in the incidence of gastric cancer over the last 10 years has not been observed in our environment where it remains as an important social problem due to its high morbidity and mortality. We proposed to evaluate if extended lymphadenectomy produces better results.
Material and methods: Between 1987 and 1991, 193 gastric cancers were diagnosed. A total of 162 (84 per cent) were reviewed 5 years after surgery. Out of them, 121 (63 per cent) could be resected, 59 with a R1 and 62 with a R2 lymphadenectomy. Characteristics of this group of 121 patients are analysed regarding age, gender, size and tumour location, histological type and surgical procedures according to tumour stage.
Results: They were analysed five years after surgery. Perioperative mortality was five cases (8·4 per cent) in the R1 group and four (6·4 per cent) in the R2 group. Morbidity was similar in both groups. Cardiopulmonary complications occurred in two (3·38 per cent) of the R1 group, and three (4·83 per cent) of the R2 group. Urinary infection occurred in five (8·47 per cent) of the R1 group and four (6·45 per cent) of the R2 group. Intra-abdominal abscesses occurred three times (5·08 per cent) in the R1 group and twice (3·22 per cent) in R2. R2 resection showed a higher incidence of suture dehiscence (six cases (9·67 per cent) vs four (6·77 per cent) in R1 group). On the other hand R1 group showed a higher incidence of surgical wound infection nine (15·25 per cent) vs seven (11·29 per cent) in R2. Recurrence occurred in 45 patients in the R1 group and 41 in the R2 group. 5-year survival was nine patients (15·2 per cent) in the R1 group and 17 (27·41 per cent) in the R2 group.
Conclusions: Best results were achieved in distal located lesion. R2 lymphadenectomy seems to improve prognosis in stages II and III. Extended total gastrectomy showed a survival rate of 37 per cent, subtotal extended 24 per cent and subtotal resection 23·6 per cent.

Percutaneous endoluminal grafting for femoro-popliteal disease: a feasibility study

M.S. Baguneid, D.J.A. Scott, A. Nevelsteen and M.G. Walker *Department of Vascular Surgery, Manchester Royal Infirmary*

Aims: A feasibility study was carried out to assess the role of a balloon mounted ePTFE graft with proximal and distal anchoring stents in patients with disabling claudication considered unsuitable for angioplasty because of the severity of the disease.

Methods: Thirty-one patients with claudication were considered suitable for treatment. All had significant disease confined to the superficial femoral artery (SFA) and satisfied the entry criteria of two or more vessel run off and minimum SFA diameter of 4 mm at stent anchor sites. Procedures were performed under local (17), epidural (2) or general (12) anaesthesia, using a 9F introducer sheath, intravascular ultrasound (IVUS) and an image intensifier.

Results: Successful deployment of the stent grafts was achieved in 23 cases, with eight failures. Five were excluded following IVUS interrogation, two after encountering difficulties with the introducer sheath and one-following device failure. Of those patients in whom graft deployment was successful primary patency was achieved in 10 (43 per cent) and secondary patency in 14 (60 per cent) at 1 year follow-up.

Conclusions: While initial results with this device have proved disappointing, current development in the design of this stent graft to one which is fully supported may result in this becoming a viable alternative to angioplasty or indeed surgery.

REDO surgery for the treatment of late complications in a 10-year follow-up of 441 reconstructive operations

Á. Balogh, R. Sipka and R. Ménesi *Albert Szent-Györgyi Medical University Department of Surgery, P.O. Box 464, H-6701 Szeged, Hungary*

The purpose of this study is to review 120 REDO operations performed at the surgical clinic of the Szentgyörgyi Medical University Szeged. These operative corrections (or late reoperations) were performed to treat late complications – reocclusion, anastomotic aneurysm, graft infection – of 441 aorto-iliac reconstructions, and were performed in a 5-year period (1986–1991). The REDO operations were done from three months to 10 years after the first interventions. Twenty-five REDO procedures (21 per cent) were performed to correct an anastomotic aneurysm, and 95 (79 per cent) to treat the reocclusion of the former reconstructed vessels. The REDO interventions proved to be necessary with a 10 per cent higher frequency after thrombendarterectomies than after bypass procedures. Following resections of the abdominal aorta due to aneurysms a REDO intervention was done in a 5 per cent lower ratio than after reconstructions to treat arteriosclerotic obliterations. The author evaluates the surgical technique of REDO surgery, gives an overview of the possibilities for surgical correction, and analyses the results of the 120 interventions.

Can clinical evaluation and noninvasive testing substitute for angiography in the evaluation of carotid artery disease?

E. Ballotta, G.D.A. Giau, T. Bottio, G. Scannapieco, E. Abbruzzese and G. Meneghetti *Istituto Clinica Chirurgica III, Sez. Chirurgia Vascolare, Università di Padova, Via N. Giustiniani 2, 35128 Padova, Italy*

Aim: The objective of this study was to prospectively assess the value of combining clinical evaluation and non-invasive testing, particularly Duplex scanning, in determining the safety and accuracy of performing carotid endarterectomy (CEA) without angiography.

Methods: During the last 9-month period, 17 patients underwent 14 CEAs without angiography. This was a prospective but non-randomized study, since precise selection of those patients subjected to CEA without angiography was practised. The indications for proceeding with CEA without angiography were as follows: 1) the progression of the carotid lesion with contralateral internal carotid artery (ICA) previously operated on with angiography; 2) renal insufficiency; 3) the need for emergency operation; 4) the need for concurrent operation in another anatomic region; 5) surgeon's preference. The patients ranged in age from 56 to 81 years, with a mean age of 72 years. All patients were preoperatively evaluated by the same neurologist and studied by duplex scanning and CT scan. Thirteen patients were symptomatic: no symptomatic patient presented with non-hemispheric symptoms. In all cases the ICA lumen reduction was ≥70 per cent. All operations were performed under general aesthesia with continuous EEG monitoring for the selective use of an intraluminal shunt (IS). All procedures were carotid eversion endarterectomy and reimplantation of the ICA in the common carotid artery. The data from ultrasound imaging were correlated with surgical findings and pathological specimens.

Results: Perioperative stroke risk and mortality rates were 0 per cent. The predicted carotid lesion was confirmed by the operative finding, at the time of exploration, with respect to high grade stenosis and the characteristics of the pathologic specimen in all 17 cases.

Conclusions: The major criticisms of the sole noninvasive evaluation are: 1) the inability to determine intrathoracic pathologic abnormalities of the carotid vessels, and 2) the possible coexistence of incidental, asymptomatic intracranial berry aneurysm or unrecognized intracranial stenotic or occlusive siphon disease. Since these exceptions are rare and may be easily overcome, CEA can be performed safely without angiography, on the basis of clinical assessment and duplex scanning solely, when the accuracy of the vascular laboratory has been carefully and scientifically established.

Duplex vein mapping of proximal deep vein thrombosis: a study of 2034 lower limbs

K. Delis, A. Lauro, V. Ibegbuna, A. Lennox, N. Labropoulos and A. Nicolaides *Irvine Laboratory, Imperial College School of Medicine, St. Mary's Hospital, London*

Aim: To evaluate the anatomic distribution, extent and patterns of proximal lower limb DVT in a large series of patients with clinically suspected DVT.

Materials and methods: The venous system of 2034 consecutive lower limbs was investigated using colour duplex imaging (ATL Ultramark 9; 5 MHz transducer). Criteria for a positive scan were: intraluminal echogenic material, non-compressibility, blood flow around a lucent filling defect, absence of intraluminal Doppler signal, continuous signal not phasic with respiration, reduced or absent flow with distal augmentation and image irregularities despite optimal settings.

Results: Supra-inguinal thrombosis was identified in 50 (2·45 per cent) limbs. Thrombosis in the common femoral vein (CFV) was detected in a total of 143 limbs (7·03 per cent). It was associated with a supra-inguinal clot in 47 limbs (32·8 per cent) and thrombosis of the superficial femoral vein (SFV) in 107 limbs (74·8 per cent), the popliteal vein (PopV) in 76 (53 per cent), the tibio-peroneal trunk (TPT) in 15 (10·5 per cent) the posterior tibial vein (PVT) in 28 (20 per cent), the peroneal vein (PerV) in 29, the soleal vein (SolV) in 17 (12 per cent) and the gastrocnemial veins (GasV) in 13 (9 per cent). Of these limbs, 41 (28·6 per cent) had sustained a previous DVT.

Thrombosis in the SFV was detected in a total of 226 limbs (11·1 per cent). It was associated with CFV and supra-inguinal thrombosis in 107 (47 per cent) and 39 limbs (17 per cent) respectively. DVT in SFV was associated with thrombosis in the PopV in 153 limbs (67·7 per cent), the TPT in 34 (15 per cent), the PTV in 60 (26·5 per cent), the PerV in 62 (27·4 per cent), the GasV in 26 (11·5 per cent) and the SolV in 31 (13·7 per cent). Of these limbs, 51 (22·5 per cent) had sustained a previous DVT.

Popliteal vein thrombosis was detected in 211 (10·3 per cent) legs and was associated with proximal DVT in 153 (72·5 per cent) of which 33 (15·6 per cent) suprainguinally; distal thrombosis involved the TPT in 46 (21·8 per cent), the PTV in 74 (35 per cent), the PerV in 75 (35·5 per cent), the anterior tibial vein (ATV) in 32 (15·1 per cent), the GasV in 37 (17·5 per cent) and the SolV in 46 (21·8 per cent).

The PTV, PerV and SolV were the most frequently thrombosed calf veins. PTV and PerV thrombosis with or without the SolV was the pattern of calf DVT most often seen. GasV thrombosis was present only in 1/3 of soleal DVT.

Only 16 per cent of limbs with suspected DVT had proximal thrombosis.

Conclusions: Thrombosis in the CFV, SFV and PopV is associated with more proximal disease in 32·8, 47 and 72·5 per cent, respectively. The more distal the thrombus the higher the likelihood of a more proximal one detected. The SFV is the most frequently thrombosed proximal vein with 22·5 per cent of affected limbs having sustained a previous thrombosis. The most frequently seen pattern of proximal thrombosis involves both the SFV and PopV with or without the PerV and PTV. Involvement of the PTV and PerV with or without the SolV is the most frequently seen pattern of multifocal calf DVT.

Treatment of arterial graft infection by in situ replacement with allogenic arterial graft

M. Gabriel, K. Pawlaczyk, Z. Krasiński, F. Pukacki and S. Zapalski *Department of the General and Vascular Surgery, University of Medical Sciences, ul. Długa 1-2, 61-848 Poznań, Poland*

The present standard therapy of aortic graft infection is connected with frequent occurrence of operative and late complications. Autogenous tissue revascularization techniques are very promising therapeutic alternatives, but their usefulness is limited by the complexity of this procedure and by the lack of suitable donor vessels. In recent years a few reports have described the possibility of replacing an infected vascular graft with an allogenic arterial graft.

From January 1996 until November 1997 nine patients with aortofemoral graft infection were treated in our department. Because of the extent of infection it was impossible to perform extra-anatomic graft. In all cases infected vascular grafts were removed and in situ arterial allograft were inserted. The allografts were taken from multiorgan donors and cryopreserved in liquid nitrogen in 20 per cent dimethylsulfoxide (DMSO).

There were no intraoperative deaths observed. One critically ill patient with severe Pseudomonas sepsis and extensive retroperitoneal abscess died on the second postoperative day, due to septic shock. One patient died in the 20th postoperative day due to myocardial infarction. In all seven survivors infection could be eradicated and during the follow-up period they remained well.

The arterial allografts seem to be the alternative in prostheses infection treatment.

High resolution ultrasound prior to endarterectomy: the accuracy of grading ICA stenosis

S.A. Jmor, T.I.S. Elatrozy, H. Elmorsy, M. Griffin and A.N.N. Nicolaides *Irvine Laboratory for Cardiovascular Investigation and Research, Imperial College School of Medicine at St. Mary's, QEQM Wing, London, UK*

Aim: The aim of this study was to evaluate the accuracy of ultrasonic B-mode images of ICA in estimating the degree of stenosis.

Material and methods: In a random consecutive series of patients scheduled for CEA routine duplex scanning was performed using ATL HDI 3000 and 7–4 MHz probe. Good quality images in B-mode (both in longitudinal and transverse views) were frozen on the screen. The percentage diameter and area reduction were calculated from each view respectively. Peak systolic (PSV) and end diastolic velocities (EDV) were measured at the proximal CCA and ICA within the jet of turbulence. The following velocity ratios were used to calculate the degree of haemodynamic stenosis (PSVic/PSVcc), (EDVic/EDVcc) and (PSVic/EDVcc). Endarterectomy specimens of the same patients were scanned immediately in a mixture of saline and gel media. The site of maximal stenosis was marked and 0·2 mm transverse pathological blocks were obtained. The duplex measurements were compared to the percentage area and diameter reduction from transverse sections of the specimens. A millimetre scale was placed next to the specimens which was captured by video. The area reduction was measured by playing the video and using the same duplex setting as above.

Results: The following table summarizes the difference in the estimated diameter stenosis using different methods in relation to that estimated from endarterectomy transverse blocks (as a gold standard). Twenty-nine out of 32 were in the region of 70–99 per cent.

Duplex method used	Percentage of cases with concordant stenosis to that estimated from the surgical specimens	Percentage of cases with disconcordant stenosis relative to that estimated from the surgical specimens
B-mode images	93%	6%
PSVica	79%	21%
EDVica	24%	76%
PSVica/PSVcca	76%	24%
EDVica/EDVcca	60%	40%
PSVica/EDVcca	76%	24%

Conclusion: The results indicate that images obtained with B-mode are the most accurate in determining the degree of stenosis. Diameter and area reduction (measured on duplex) might be more appropriate parameters to be used in studies that evaluate the sensitivity and specificity of ultrasound with angiography as gold standard.

Acute normovolaemic haemodilution in repair of abdominal aortic aneurysm: autolologous transfusion and cost reduction

D.R. Lewis[1], S. Winter[1], M. Nevin[2], F.C.T. Smith[1], R.N. Baird[1] and P.M. Lamont[1] [1]*Department of Surgery,* [2]*Department of Anaesthetics, Bristol Royal Infirmary, Bristol, UK*

Aim: To review the practice of acute normovolaemic haemodilution (ANH) in routine abdominal aortic aneurysm (AAA) repair in a single vascular unit with analysis of financial implications.

Patients and methods: Retrospective analysis of case notes, operation records and anaesthetic charts was undertaken for 80 randomly selected patients who had undergone routine AAA repair (1990–1997). Demographic and operative details were noted along with blood cross-matching, blood loss and per and postoperative transfusion practice. Pre and postoperative haemoglobin (Hb) concentration and packed cell volume (PCV) were recorded. Outcome of surgery was assessed by observing 30-day mortality, postoperative morbidity and length of hospital stay. Economic analysis was used to estimate potential cost savings.

Results: Of 80 patients studied 72 (90 per cent) had complete records suitable for analysis. Thirty-two patients had ANH preoperatively (group 1), 40 did not (group 2). Mean (range) volume of ANH blood for autologous transfusion was 700 (400–1200) ml. Of all the parameters measured only the number of units of blood cross matched preoperatively (median values: four units group 1 vs six units group 2) (Mann–Whitney, P=0·0035) and the number of units transfused peroperatively (median values: 0·5 units group 1 vs two units group 2) (Mann–Whitney, P=0·0065) were significantly different. Comparing the cost of equipment used for ANH and the cost of cross matching heterologous blood there is a saving of £70 per operation if ANH is used.

Conclusion: The results suggest that ANH is a safe procedure prior to routine AAA repair and has definite economic advantages over heterologous transfusion. The theoretical decreased risk of infection and transfusion reaction as well as increased oxygen carrying capacity of autologous blood warrant further research.

The prevalence of Factor V (G1691A) and methylenetetrahydrofolate reductase (C677T) gene mutations in Turkish patients with arterial thrombosis

F. Özmen, M.M. Özmen, E. Akar, N. Özalp and N. Akar
Department of Paediatric Molecular Genetic, Ankara University Medical School and Surgical Department, Numune Hospital, Ankara, Turkey

Although Factor V G1691A (FV) mutation is a well recognized genetic risk factor for venous thrombosis, its role in patients with arterial thrombosis needs to be clarified. As the individuals carrying this mutation may be asymptomatic, there might be a possible interaction with other risk factors such as point mutation at C677T in the 5'-10'-methylenetetrahydrofolate reductase (MTHFR) gene. FV and MTHFR are frequent in the general population and coinheritance may further increase the risk of thrombosis. Therefore, we investigated the prevalance rate of FV and MTHFR gene mutations in patients with arterial thrombosis and healthy controls. All subjects and controls were from Central Anatolia. Fifteen (3F) patients with the median (range) age of 59 (20–77) years and 90 (50F) with the median (range) age of 31 (20–73) years were studied. DNA was extracted using conventional methods followed by PCR amplication and restriction endonuclease digestion. Digested PCR products were identified using agarose gel and stained with ethidium bromide.

Of the 15 patients with arterial thrombosis four (27 per cent) had heterozygote FV gene mutation whereas eight (53 per cent) had heterozygote MTFR and one had homozygote MTHFR gene mutation. Out of 90 healthy controls, seven (8 per cent) had FV gene mutation whereas 29 (32 per cent) had heterozygote MTFR and six (7 per cent) had homozygote MTHFR gene mutations. Coinheritance of heterozygote FV and MTHFR was found in 75 per cent of patients with arterial thrombosis which was 43 per cent in healthy controls.

The increased rate of prevalence and coexistence of both FV and MTHFR found in this group of patients suggesting that these mutations might increase the risk of arterial thrombosis but it needs further investigation.

In situ repair or extra-anatomic reconstruction for treatment of aorto-enteric fistulas

E.H.J. Paes and J.F. Vollmar *Department of Vascular Surgery Marienhospital, University Aachen Zeise 4, 52066 Aachen, Germany*

Based on 23 own observations and 208 patients with aorto-enteric fistulas (AEF) collected from the literature, actual diagnostic methods and its surgical approach are discussed.

The most frequent location both of primary and secondary aorto-enteric fistulas is the endpart of the duodemum. In the group of secondary AEF the paraprosthetic type represents the most frequent morphological finding. The choice of surgical repair is still controversial. Numerous surgeons however insist on a radical repair (Type A: restoration of the intestinal tract, complete removal of the vascular prosthesis, blind closure of the infrarenal aortic stump and axillo-bifemoral bypass. As an alternative surgical approach an in situ repair is presented (Type B: closing of the intestinal defect, partial exchange of the inserted vascular prosthesis, an encircling omentum sleeve covering the prosthesis and anastomoses).

Type A is loaded with a high operative mortality (52 per cent) and frequent secondary complications (e.g. recurrent AEF, bleeding from the aortic stump). The Type B repair offers a time-saving procedure with a reduced operative mortality (22 per cent) and a better outcome for the patients. The only contraindication for this method is the presence of an extensive infection of the retroperitoneal space including the vascular prosthesis.

Patients with low-grade aortic graft infection benefit from partial graft resection and in situ repair.

Long-term results of 716 PTFE grafts for dialysis: analysis of different graft sizes and configurations

J.R. Polo, M.C. Menárguez, J. Sanabia, A. Flores, J.A. Rueda and J. Polo *Vascular Access Unit, Hospital General Universitario Gregorio Marañón, Dr Esquerdo 46, 28007, Madrid, Spain*

Aim: The purpose of this presentation is to analyse the complication rate of 716 PTFE grafts for dialysis, and calculate their primary and secondary patency rates.

Material and methods: Between 1981 and 1997 2565 vascular accesses were performed: 1259 radiocephalic arteriovenous fistulas (AVF) (67 per cent), 468 upper arm AVF (18 per cent), 82 dacron cuff catheters (3 per cent) and 716 PTFE grafts (28 per cent). Anatomical positions of grafts were as follows: upper-arm (6–8 mm): 324 (45 per cent); upper-arm (6 mm): 184 (26 per cent); straight forearm (6 mm): 96 (13 per cent) curve forearm (6 mm): 49 (7 per cent); brachiojugular (6 and 6–8 mm): 51 (7 per cent); femoro-fermoral (6–8 mm): 12 (2 per cent). Retrospective study. Parametric analysis was done with Student's *t*-test. Graft surviva was calculated using the life-table method.

Results: Overall complication rate was 0·49 episodes per graft-year o follow-up. Complication rate (episodes per graft-year) was significantl lower in 6–8 mm upper arm grafts (0·33) ($P<0{\cdot}001$), compared with th other grafts (6 mm upper-arm = 0·57; 6 mm straight forearm = 0·62 brachiojugular = 0·72; 6 mm curve forearm = 0·74). Overall primar patency was 70 per cent, 34 per cent and 12 per cent at 1, 5 and 10 years Overall secondary patency (after successful rescue surgery for complications) was 86 per cent, 66 per cent and 39 per cent at 1, 5 and 10 years Best patency rates were observed in 6–8 mm upper-arm grafts: primary 92 per cent, 52 per cent, 24 per cent at 1, 5 and 10 years; secondary, 9 per cent, 79 per cent and 54 per cent at 1, 5 and 10 years.

Conclusions: 1: 6–8 mm upper-arm grafts (8 mm grafts tapered to 6 mm at the arterial side) show the lowest complication rate and best long-term survival. 2: Brachiojugular grafts can be an alternative in cases of non dilatable subclavian vein stenosis or occlusion.

Non-operative treatment of false aneurysms using percutaneous injection of fibrin adhesive

S.P.K. Payne and H. Loose *Northern Vascular Centre, Freema Hospital, Newcastle-upon-Tyne, UK*

Traumatic false aneurysms often require operative repair if duplex-guided compression fails. We describe a percutaneous technique of occlusio which preserves the artery of origin and avoids the use of metallic coil and endovascular stents.

This technique was attempted in 13 patients with peripheral false arterial aneurysms where duplex-guided compression had failed over an 18 month period. In each case an angioplasty catheter was placed across th neck of the aneurysm and inflated until flow within the sac was occlude Duplex scanning confirmed this and under ultrasound guidance, 3 ml o tissue adhesive (Beriplast – P) was injected percutaneously into the sa during flow occlusion. Once thrombus production was confirmed o duplex with the angioplasty balloon deflated, the needle and angioplast catheter were withdrawn.

Ten femoral, two popliteal and one posterior tibial aneurysms we treated with this technique. Two femoral aneurysms demonstrated min flow on completion, but complete occlusion on repeat duplex at 24 hour One patient developed a small false aneurysm at the site of insertion o the angioplasty catheter which closed spontaneously. One patient died day 2 (cause unrelated to this technique). In all cases the false aneurys was successfully occluded with preservation of the artery of origin.

This technique potentially avoids operative repair of false arteri aneurysms in patients where duplex guided compression has failed and associated with minimal complications.

Colonoscopy with biopsy after aortic surgery: a unique study of the incidence of colonic ischaemia

M. Welch, M.S. Baguneid, D. Dodd, M. Bukhari, G.D. Griffiths and M.G. Walker *Department of Vascular Surgery, Manchester Royal Infirmary, Manchester, UK*

Aims: Colonic ischaemia is a well documented complication of abdominal aortic reconstruction. This is the first prospective study in which all patients have had routine pre- and postoperative colonoscopy and biopsy, in order to determine the true incidence and implications.
Methods: Fifty-six patients undergoing elective infrarenal aortic surgery, 28 for aneurysm and 28 for occlusive disease, were colonoscoped and biopsied pre and one week postoperatively.
Results: All patients had normal macroscopic and microscopic appearances on preoperative biopsies. A 30 per cent incidence of postoperative colonic ischaemia was identified by histology (16/53 patients), almost half of these (7/16) having normal macroscopic appearances. Two factors exhibited a statistically significant association with development of ischaemia: prolonged cross-clamp time (mean of 44·75 vs 35 minutes, $P<0·05$, Mann–Whitney U test) and postoperative diarrhoea (88 per cent vs 13 per cent, $P<0·001$, Fisher's exact test). Co-morbidity was much higher in those patients with ischaemia (81 per cent vs 13 per cent, $P<0·005$, Fisher's exact test). Overall morbidity was significantly greater in the aneurysm group (46 per cent vs 21 per cent, $P<0·05$, Fisher's exact test).
Conclusion: Colonic ischaemia after aortic reconstruction is a much more common occurrence than previously reported, and though mild and transient in many cases, is still associated with significant morbidity. When suspected, colonoscopy with biopsy is recommended.

Oesophageal epidermoid carcinoma: results of surgery after neoadjuvant radiochemotherapy

*M. Adham, *J. Baulieux, †J.P. Gerard, E. Delaroche, *N. Berthoux and *C. Ducerf *Department of General, Gastrointestinal Surgery and Liver Transplantation, Croix Rousse Hospital, Lyon, France. †Department of Radiotherapy, Centre Hospitalier Lyon Sud Lyon, France

While surgery still remains the treatment of choice for oesophageal epidermoid carcinoma, there was no improvement of the survival rate in the past decades with 18 per cent 5-year actuarial survival. The aim of this study was to evaluate the interest of surgery after neoadjuvant radiochemotheraphy to 1) increase the resection rate; 2) improve the actuarial survival rate; 3) increase the disease-free survival (DFS); 4) avoid mutilating surgery. From February 1987 to September 1997, 55 patients (49 men and six women) with a mean age of 58·8 years (from 38 to 77) received oesophageal resection after neoadjuvant treatment. In eight cases there was a previous history of ENT epidermoid carcinoma. Tumour location was: upper 1/3 *n*=19, middle 1/3 *n*=22, lower 1/3 *n*=9 and double localization in upper and lower 1/3 *n*=5. Impassable stenosis was observed in 20 cases. Thirty-five patients had endosonography, and tumour classification was mainly uT3 *n*=25 (45·5 per cent), uT4 *n*=6 (11 per cent) and uN1 *n*=25 (45·5 per cent), uN2 *n*=6 (11 per cent), the other patients were: uT0 *n*=1, uT1 *n*=1, uT2 *n*=4, uTx *n*=3, uN0 *n*=5, uNx *n*=4. Neoadjuvant treatment included two courses of chemotherapy 5-FluoroUracil (1 g/m^2/day) and Cisplatyl (25 mg/m^2/day) from day 1 to day 5, and from day 21 to day 26 where half dose of 5FU was given. Radiotheraphy was done from day 21 to day 36 giving a total of 36 grays. Full neoadjuvant treatment was possible in 67·3 per cent of cases, radiotherapy was completed in 85·5 per cent, and uneventful course was achieved in 56·4 per cent. Surgery was performed one month after the end of radiotherapy (at day 60). Tumour resectability was 96·4 per cent, only two patients had surgical exploration without tumour resection. Complete (curative) resection was achieved in 45 cases (82 per cent), and in eight cases (14·5 per cent) palliative resection was done. Forty-seven patients had gastroplasty and two had coloplasty. Three field lymphadenectomy was done in 38 cases (69 per cent) and two field lymphadenectomy in 15 cases (27 per cent). Operative mortality was nil, and hospital mortality was 7·3 per cent. The postoperative course was uneventful in 45·5 per cent of patients, complications that occurred were mainly pulmonary (34·5 per cent) and recurrent nerve palsy (23·6 per cent). Pathological tumour classification (AJCC 1988) was: Stage 2a *n*=6, Stage 2b *n*=3, Stage 3 *n*=8 (14·5 per cent), Stage 4 *n*=13 (24 per cent), and in 23 cases (42 per cent) the tumour was totally (or almost) sterilized (R±). Larynx preservation was achieved in 10 of 12 patients with theorectical indication of total pharyngolaryngo-oesophagectomy. The overall actuarial survival rate was 27 per cent and 22 per cent at 4 and 9 years. The DFS was 28 per cent and 25 per cent respectively Sixteen patients died with local or metastastic recurrence, and 19 are living (17 are disease free and two with metastasis). In the group R±, the actuarial survival rate was 53 per cent and 46 per cent at 4 and 9 years, and the DFS was 46 per cent and 47 per cent respectively. Six patients died without recurrence and 12 are living and disease free. Neoadjuvant treatment is well tolerated by almost all patients when carefully selected. It appears that this combination therapy increases tumour resectability, it can allow in some cases laryngeal preservation. Significant improvement of the actuarial survival rate and DFS is observed in the R± group.

Barrett's oesophagus: indications for resection

D. Benchimol, M. Chazal, A. Myx, J.L. Bernard, H. Richelme and A. Bourgeon *Service de Chirurgie Abdominale et Thoracique Hôpital de l'Archet 2 B.P. 3079 06202 Nice Cédex 3, France*

The aim of this retrospective study was to assess the indications and the results of oesophageal resection for Barrett's oesophagus (BO).

From 1992 to 1997, 20 patients with histologically proven BO underwent resection: 19 males, 1 female, mean age 66. During the same period, 145 oesophagectomies were performed for other reasons, and five patie with a BO underwent an antireflux procedure. Oesophagectomy was p formed via abdominal and right thoracic approach in nine cases, with thoracotomy in seven cases and via a left thoracic approach in four cas

Postoperative pathology showed 19 adenocarcinomas and one h grade dysplasia (HGD). Five patients had previous diagnosis of BO, whom three were under an endoscopic surveillance programme. T pathology of these three patients showed one HGD and two T_1 tumou while in the two others, tumour was classified T_3 N_1.

There were two postoperative deaths (10 per cent) from pulmon complications. The 3-year actuarial survival rate was 48 per cent.

In conclusion, resection is rarely indicated for BO, and mainly invasive carcinoma. Long term results can be improved if oesophag tomy is indicated for HGD or early stage carcinoma, condition possi diagnosed by an endoscopic surveillance programme of BO.

Laparoscopic approach for redo antireflux surgery

M. Fein, K.-H. Fuchs, J. Heimbucher, S.M. Freys and A. Thied
Chirurgische Universitätsklinik, Josef-Schneider Str. 2 97080 Würzburg, Germany

Background: In general, reoperations after failed antireflux surgery performed as an open transthoracic or abdominal procedure and lapa scopic refundoplication is still controversial.
Aim: To analyse the surgical and functional results following lapa scopic redo antireflux surgery.
Methods: Fourteen patients (nine male, five female; age: 13–52 yea have been scheduled for laparoscopic refundoplication since 12/93. these, 11 had previous antireflux operations performed in other hospit Three of the 110 patients (2·7 per cent), who had antireflux surgery in clinic, needed a second operation. The indication for surgery was rec rent reflux in 10 and severe dysphagia in four patients. Patients were c sidered for a laparoscopic approach, if they had previous laparosco antireflux surgery (*n*=5), only attempt for an open fundoplication (*n*= or one or more open operations with gastropexia (*n*=5). Follow-up exa inations were done after 1–4 years (median: 19 months).
Results: A laparoscopic refundoplication was completed in eight of 14 patients (57 per cent). Because of severe adhesions conversion w necessary in three patients following fundoplication and in three patie following gastropexia. Outcome at follow-up examination was rated go or excellent in all patients. No one complained of dysphagia and regur tation. Mild heartburn was present in two patients, and occasional g bloat in four patients.
Conclusion: Laparoscopic refundoplication is useful especially patients following laparoscopic fundoplication. The results are similar those with the first antireflux procedure. Refundoplication in a patient f lowing an open procedure frequently requires an open procedure.

Long term clinical evaluation of oesophageal reconstruction

Z. Gerzić, J. Knezević, P. Pesko, T. Randelović, N. Radovanović A. Simić and P. Sabljak *Department of Esophagogastric Surgery, First Surgical University Hospital, Clinical Centre of Serbia, Koste Todorovića st. 6, 11.000 Belgrade, Yugoslavia*

Introduction: During a 25 year period (between 1964 and 1990) 7 patients underwent oesophageal reconstruction. The most common reco structive operations were: long segment isoperistaltic colon substituti after corrosive ingestion not responding to other methods of treatme distal esophageal interposition of the jejunum and gastric tuba (cervic EGA). To assess long-term results of various methods of reconstructi we randomized 150 patients (22 per cent) for control study. Only cooperative patients arrived to the clinic for an interview and the contr examination. There were 10 patients operated for carcinoma and patients with benign lesions operated in the period of 5 to 25 years ago

Methods: All operated patients were divided in five groups: right colon oesophagoplasty (17 patients), left colon oesophagoplasty (20), gastric tube (10), interposition of the jejunum (10) and Roux-en-Y reconstruction (five patients). Ten healthy volunteers were examined in the same time as a control group. The clinical evaluation has been achieved by a personal interview (side effects, ability to swallow and eating habits), clinical examination (body weight, barium swallow and endoscopy) and functional tests (radionuclide scintigraphy – transit time and clearance). All examined patients were classified in three groups – excellent, good and poor. In categorizing the patients according to our results, excellent and good patients were selected who had no symptoms related to feeding, clinical evaluation and functional tests were negative. The outcome was considered good to poor if the patients occasionally experienced temporary symptoms, medium clinical results and tests and poor with severe symptions, clinical results and test which cause an incapacitation and need for another corrective operation.
Results: In overall long-term (5–21 years) control examination of 62 patients, 69·35 per cent had an excellent to good results, 25·80 per cent had a good to poor results and only 4·8 per cent had poor results. The best long term results (8–10 years after surgery) we found in the group of patients with short jejunal interposition. All these patients showed almost normal behaviour and normal clinical and functional tests. On the second place is long isoperistaltic left colon substitution (5–21 years). After this type of reconstruction the patients must modify their eating habits but had no swallowing difficulties. Regurgitation and gastrocolic reflux with colitis were not common but we found colonic stasis in almost 50 per cent of patients. Only 5 per cent of patients had persistent weight loss. In most of the patients propulsive activity of the colon was difficult to quantify. In the group of patients with right colon reconstruction the long term results were a little better in the left colon. On the third place we found long term results after gastric tube reconstruction (5–10 years). Reflux esophagitis is dependent of the level of EGA but we found it in 20 per cent in high anastomosis.
Conclusion: In comparing our results with other series bypass reconstruction has some advantage because of vagotomy after oesophagectomy and also postoperative mortality is higher than in bypass reconstruction.

Has the expansion of laparoscopy modified the medical habits in the treatment of the gastro-oesophageal reflux

P. Hauters, A. Lochegnies, C. Lequeux, A. Nakad, E. Farchakh and M. Deffrennes *Clinique Notre-Dame, 9 Avenue Delmée, 7500 Tournai, Belgium*

Between 1992 and 1996, 42 patients had a Nissen fundoplication for gastro-oesophageal reflux. There were 29 men and 13 women, the median age was 37 years (range: 25–65). One patient was lost to follow-up. The other patients were evaluated in December 1997, the median follow-up was 30 months (range: 12–72). We recorded one bad, four good and 36 excellent results. We distinguished between two groups to determine whether the expansion of laparoscopy had modified or not the management of the patients presenting with peptic oesophagitis. Group A consisted of 15 patients operated on between 1992 and 1994 and group B of 27 patients operated on between 1995 and 1996. A minority of patients (5/15=33 per cent) were treated by laparoscopy in group A and a majority (22/27=81 per cent) in group B ($P<0\cdot005$). The Nissen fundoplication represented 1·2 per cent (15/1216) of the global surgical activity in group A and 2·9 per cent (27/925) in group B ($P<0\cdot01$). The postoperative results were equivalent in the two groups. Patients of group A had complained of gastro-oesophageal reflux for 7±5 years and patients of group B for 5±3 years (NS) before being referred for surgery. The number of gastroscopies and the length of the medical treatment before surgery were also equivalent in the two groups: respectively 7±2 gastroscopies and 32±15 months in group A vs 6±3 gastroscopies and 26±12 months in group B (NS). It has to be noted that several patients were referred to the surgeon by a friend or by the general practitioner while they had never been informed by the gastroenterologist about the potential benefit of a surgical operation. That situation occurred in three patients (20 per cent) of group A and in eight patients (29 per cent) of group B (NS). In our experience, Nissen fundoplication is a successful procedure in 97 per cent of the patients. With the expansion of laparoscopy, we have noted that the patients are not referred quickly to surgery but that the number of operations performed for gastro-oesophageal reflux has increased significantly. Finally, it is clear that some gastroenterologists still have to be convinced of the role of surgery in the treatment of the gastro-oesophageal reflux.

Adenocarcinoma on Barrett's oesophagus: a series of 44 resections

P. Lozac'h, Ph. Topart, A. Volant and R. Saad *Service de Chirurgie Viscérale 1, CHU de la Cavale Blanche, 29609 Brest Cédex, France*

Introduction: The incidence of lower esophageal adenocarcinoma is increasing. The responsibility of Barrett's oesophagus may be suspected. This study reviews the results of a surgical approach.
Methods: Between 1982 and 1997, 44 adenocarcinomas on Barrett's oesophagus were resected among 120 type I and II adenocarcinomas. The mean age of the 40 men and four women was 65 (39 to 86). Hiatal hernia was present in 25 patients and gastro-esophageal reflux also in 25. Barrett's oesophagus has been previously diagnosed and monitored in five patients. Preoperative radio-chemotherapy was given to four patients. Surgical procedures included 39 Ivor Lewis, four transhiatal esophagectomies and one total gastrectomy.
Results: Thirteen cancers were spread over the entire Barrett's oesophagus, seven were located at the upper end and 23 in the two lower thirds. Twelve tumours were staged T1, five T2 and 25 T3 with 48 per cent N+ tumours. Severe or moderate dysplasia was found around the cancer in 17 resected specimens. Two patients died postoperatively. Among Ivor Lewis operations 32 out of the 39 patients had no complications. The 5-year actuarial survival is 24 per cent.
Conclusion: Total resection of the Barrett's oesophagus is essential in order to remove surrounding dysplasia. A two field oesophagectomy allows thoracic and abdominal lymph node resection.

Flow cytometric DNA analysis and p53 protein expression show a good correlation with histological findings in patients with Barrett's oesophagus

L.F. Martinez de Haro, P. Parrilla and F. Sanchez *Department of Surgery, University Hospital V Arrixaca, El Palmar, 30120 Murcia, Spain*

Introduction: There is a considerable degree of subjectivity and, therefore, substantial inter-observer and intra-observer disagreement in the diagnosis and grading of dysplastic lesions in Barrett's oesophagus. The aim of this study was to evaluate the usefulness of DNA flow cytometry and immunohistochemical staining for p53 protein as objective methods to complement the conventional histological diagnosis of dysplasia in this disease.
Methods: Formalin-fixed, paraffin-embedded tissue of 55 patients diagnosed of Barrett's oesophagus were processed for flow cytometric measurements (ploidy, proliferation index) and p53 immunostaining.
Results: Both the proliferation index measured by flow cytometry and the positivity of the staining for p53 showed a statistically significant increase throughout the sequence: no dysplasia – indefinite for dysplasia – low-grade dysplasia – high-grade dysplasia – adenocarcinoma. Only in the samples with severe histological alterations aneuploid cell populations were found. There is also a highly significant correlation between the results of the cytometric study and the positivity in the staining for p53.
Conclusions: The use of these procedures may play an important role in the evaluation of patients with Barrett's oesophagus. If we consider that staining for p53 is technically simple, economical and quick, and represent a procedure available to most pathology laboratories, it seems obvious that the use of this staining must play a role as a biomarker in this disease. We show the possibility of obtaining adequate results for the cytometric analysis with small formalin-fixed, paraffin-embedded biopsies, following a strict protocol for acceptance of the tissue samples and/or histograms obtained.

Flow cytometric DNA analysis and p53 protein expression improve the identification of Barrett's oesophagus patients that require a more accurate endoscopic surveillance

P. Parrilla, L.F. Martínez de Haro and F. Sanchez *Department of Surgery, University Hospital V Arrixaca, El Palmar, 30120 Murcia, Spain*

Introduction: Regular endoscopic surveillance is recommended for patients with Barrett's oesophagus to detect dysplasia and to diagnose carcinoma while it is in an early and possibly treatable stage. However, there are numerous controversial aspects regarding the natural history of dysplasia in this disease. Our objective was to investigate the usefulness of DNA flow cytometry and immunohistochemical staining for p53 protein in order to define subgroups of patients showing similar histological findings but with a different malignancy potential.
Methods: We reviewed the evolutive behaviour of 81 patients with this disease. For the present study we selected 36 of these 81 patients, including all those who at some time in the follow-up had had a diagnosis of dysplasia in any of its grades (*n*=23). Formalin-fixed, paraffin-embedded tissue of these patients were processed for flow cytometry measurements (ploidy, proliferation index) and p53 immunostaining.
Results: Only in the group of patients with 'indefinite dysplasia' we did find statistically significant differences between the samples from patients with and without progression to more severe lesions, as far as both flow cytometry and staining for p53 are concerned.
Conclusions: Our results suggest that these procedures are capable of distinguishing between a real, although incipient, neoplastic process and morphological changes of a reactive or reparative type.

Quality of life and function of the oesophageal substitute after oesophagectomy and oesophago-gastrostomy for oesophageal cancer

G. Zaninotto, M. Costantini, A. Ruol, M. Anselmino, M. Renier, D. Molena, L. Nicoletti, D. Casara, S. Merigliano and E. Ancona
University of Padua, Istituto di Chir. Generale II, Italy

The recently proposed Gastrointestinal Quality of Life Index (GIQLI)[1] was used to evaluate the outcome of subtotal oesophagectomy and gastric pull-up in 45 consecutive patients (33 male, 12 female, median age 64 years), at a median 13 months after surgery. All the patients were recurrence-free; patients with anastomotic stricture were excluded. The GIQLI was based on a questionnaire containing 36 questions, each of which was attributed a score from 0 (=always) to 4 (=never), regarding foregut symptoms (heartburn, regurgitation, dysphagia, belching), as well as physical, emotional, social and therapeutic aspects of postoperative life in these patients. A matched group of 71 healthy subjects (41 male, 30 female, median age 61 years) served as controls. A subset of 15 patients (ten male and five female, median age 64 years), 10 with moderate to severe foregut symptoms and five with no symptoms, was also evaluated by means of endoscopy with oesophageal and gastric biopsies, supra-anastomotic oesophageal pH- and bilirubin monitoring (Bilitec®), gastric bilirubin monitoring, biliary scintigraphy with ^{99m}Tc-HIDA and gastric emptying scan of a semi-solid meal.
Results: The overall GIQLI score did not differ between patients and controls (120·5, r. 92–142, vs 127, r. 86–143, *P*=ns); however, the partial 'symptom' score was lower in patients than in controls (16, r. 9–20, vs 20, r. 12–20, *P*<0·05): 17 out of the 45 patients (38 per cent) were considered as having moderate to severe foregut complaints (symptom score ≤15). The partial score regarding the patients' physical status also differed from controls (*P*<0·04), whereas the emotional, social and therapeutic scores were similar in patients and controls. In the group of patients who underwent functional evaluation, the presence of oesophagitis, gastritis and abnormal acid gastro-oesophageal reflux did not differ between symptomatic and asymptomatic patients, whereas the percentage time of the presence of bilirubin in the intrathoracic stomach and in the oesophagus was significantly higher in symptomatic patients (*P*<0·01): in particular, an abnormal oesophageal exposure to bilirubin was found in eight symptomatic patients, but only in one asymptomatic case (*P*<0·05). An abnormal ^{99m}Tc-HIDA biliary scintigraphy and delayed gastric emptying tended to be more frequent among symptomatic patients, though the difference did not reach statistical significance.
Conclusion: The overall quality of life in patients who undergo subtotal esophagectomy and intrathoracic oesophagogastrostomy for esophageal cancer is good and does not differ from that of healthy controls, although physical performance is impaired and some foregut symptoms are recorded. These symptoms seem to be mainly related to the presence of bile reflux and, possibly, to abnormal gastric emptying.

Treatment of bile leak following laparoscopic cholecystectomy: the significance of the bile duct of Luschka

I. Asztalos, E.M. Gamal, P. Metzger, I. Szántó, Á. Altorjay, A. Vörös, I. Rózsa and J. Kiss *H.I. University For Health Sciences, Department of Surgery, Budapest, Hungary, 1389 Budapest, Szabolcs u. 35, P.O. Box 112, Hungary*

Introduction: The treatment of bile leak following laparoscopic cholecystectomy (LC) depends on the severity of the injury and the site of the leakage. Injury can occur to the extrahepatic biliary tree, excessive dissection to the liver bed, to an undiscovered bile duct of Luschka. Another cause is the leak due to insufficient clip application to the cystic duct.
Methods and results: During the period 1991–1996, 11 bile leaks occurred following 2400 successful laparoscopic cholecystectomies. In two cases bile extravasation occurred because of insufficient clip application, and in nine cases minimal biloma and leakage was observed. All leaks had been indicated by the drain, which was routinely inserted in the subhepatic region. Urgent laparotomy and re-ligation of the cystic duct stump was performed in two cases due to clinically manifest bile-peritonitis and diffuse bile collections in the abdominal cavity. In seven cases the clinical observation and follow-up ultrasound examinations proved to be sufficient, the amount of bile leak decreased continuously, and the discharge disappeared 2–3 days following the operation, indicating that the bile leak was due to injury to bile duct of Luschka. In two other cases the leak persisted for 6–7 days, with constant amounts without clinical manifestations of peritonitis, and ERCP showed bile duct of Luschka that communicated with the drain, and bile discharge regressed in 8–9 days postoperatively, and then ceased.
Conclusion: Following LC, the clinical signs, ultrasound, ERCP and the observation of the tendency of bile leak through the drain can determine the tactics to be followed. Whenever manifest bile peritonitis and diffuse fluid collections are present, this indicates a serious injury to the bile ducts or a technical problem with the clips applied to the cystic duct, thus and urgent ERCP and endoscopic sphincterotomy, laparotomy or re-laparoscopy should be performed. Decreasing rate of the leak without signs of peritonitis indicates an injury to a bile duct of Luschka, which can be treated conservatively.

Five years experience with laparoscopic herniorraphy

A. Bobrzyński, A. Budzyński, K. Rembiasz, W. Dutkiewicz, Z. Biesiada and J. Krzywoń *Second Department of General Surgery, Collegium Medicum of Jagiellonian University, ul. Kopernika 21, 31-501 Krakow, Poland*

We present our 5 years of experience with laparoscopic hernia repair, development of currently used techniques and concepts. From January 1993 to January 1998 we performed 572 laparoscopic herniorraphies in 519 patients. 2/3 of all hernias were indirect, nearly 1/3 direct inguinal. There were only three femoral and two incisional hernias; 9·27 per cent (53) of our patients were submitted to laparoscopy for bilateral hernia and 6·47 per cent (37) for recurrent one. Patients ranged in age from 15 to 84 years (mean 43). At the beginning the technique was used only in limited number of cases particularly lean men with small hernia. Since then we started to practice it routinely and laparoscopy composes now more than 70 per cent of elective hernia surgery. We encountered no complication requiring laparotomy. We had three cases of intraoperative complication – transection of inferior epigastric vessels. In two patients we successfully stopped bleeding laparoscopically by clips application, one required 3 cm incision in groin area with open ligation of bleeding vessel. In the majority of patients the postoperative period was smooth and uneventful and they were able to regain normal activity after suture removal. Postoperative complications were infrequent and in most cases minor and self-resolving like transient hyperestesia, pain, haematoma or seroma in the groin area. In nine patients seromas had to be drained percutaneously in 1–8 sessions. We observed 23 (4·02 per cent) recurrences. Almost all of them appeared within 1 year after operation. Most recurrences come from a period of time when we used small mesh covering only existing abdominal wall defect. The currently used modified technique with extensive tissue dissection and mesh covering whole groin area is associated with markedly lower recurrence rate. Even though we think that every patient with primary, single hernia is a good candidate for laparoscopic repair, in case of bilateral or recurrent hernia laparoscopic herniorraphy should be particularly recommended.

Does laparoscopic ultrasound identified lymph node status of upper gastro-intestinal malignancy have prognostic value?

D.M. Bruce, M.E. Flett and K.G.M. Park *Ward 50, Aberdeen Royal Infirmary, Foresterhill, Aberdeen, UK*

Aim: We have previously shown that laparoscopy, combined with high frequency, high resolution ultrasound improves staging of gastro-oesophageal malignancy when compared to conventional techniques (clinical, endoscopy, abdominal ultrasound and CT scans). This study examined the impact on tumour recurrence and patient survival of intra-abdominal lymph node status identified by laparoscopic ultrasound (LUS).
Materials and methods: Forty-four patients with tumours, deemed resectable, by conventional staging, who underwent LUS, were available for follow-up. Thirty-seven had proceeded to resection and seven underwent palliative therapies having been 'upstaged' by LUS. Data regarding LUS nodal staging, tumour recurrence and patient survival were prospectively collected. All patients were reviewed until death or at least one postoperative year. Nodal group comparisons are between tumours staged N_0 compared with N_1 or 2 by UICC criteria (1992).
Results: Overall there was a 58 per cent 1-year cumulative survival (median 14 months; standard error [SE] 0·08). However, those patients proceeding to resection had 67 per cent 1-year survival (median 17 months; SE 6) which was greater than the palliative therapy group, with no 1-year survivors (median 4 months; SE 6). LUS defined nodal status predicted no significant difference in survival of the overall group or gastric/oesophageal subgroups. However, there was a trend towards prolonged survival in the node negative group (median 29 months; SE 9 compared with 13 months; SE 4 in the positive group). Disease-free survival was greater in LUS node negative patients (26 months; SE 2 compared with 13 months; SE 4; $P<0{\cdot}005$).
Conclusion: LUS staging allows us to predict the likelihood of recurrence of gastro-oesophageal malignancies. This may prove a useful tool for the appropriate allocation of patients to primary and adjuvant therapies.

Open vs laparoscopic Heller-Dor procedure for oesophageal achalasia: a comparative functional study

G. Castrucci, V. Porziella, P.L. Granone and A. Picciocchi *Department of Surgery I, 'A. Gemelli' Medical School, Catholic University of Rome, Rome, Italy*

Aim: To compare the clinical outcome and the functional results of laparoscopic vs 'open' Heller-Dor procedure.
Material and methods: Our series consists of 30 patients affected by primary oesophageal achalasia; preoperative oesophageal manometry confirmed the diagnosis in each case. All patients underwent laparoscopic (10 patients, A-group) or 'open' surgical treatment (20 patients, B-group). Clinical outcome and functional results were evaluated in all patients, by means of clinical interview, oesophageal manometry and 24-hour pH-monitoring, 6 months after surgery.
Results: Excellent (no food regurgitation or dysphagia) or good (no food regurgitation, dysphagia less than once weekly) clinical outcome was observed in 90 per cent of A-group (9/10 patients) and in 95 per cent of B-group (19/20 patients). One patient for each group had a slight dysphagia but ate an unrestricted diet.

	Preoperative LES pressure (mean±SD)	Postoperative LES pressure (mean±SD)	TRT % (mean±SD)
A-Group	42·0±12·8 mmHg	18·2±3·7 mmHg	1·6±2·0
B-Group	39·2±15·5 mmHg	13·2±5·4 mmHg	3·2±5·7

A statistically significant postoperative reduction of lower oesophageal sphincter (LES) basal pressure was observed in both groups (A-group, $P<0.0001$; B-group $P<0.0001$). Postoperative LES basal pressure was higher after laparoscopic treatment than after 'open' approach ($P=0.01$).

Similar incidence of postoperative pathological reflux (Total Reflux Time [TRT] >3·4 per cent) was detected by 24-hour pH monitoring (A-group 3/10 patients, 30 per cent; B-group 4/20 patients, 20 per cent). A lower mean value of TRT was detected in laparoscopic group, although it was not statistically significant.

Conclusions: Our results confirm that clinical outcomes of laparoscopic and 'open' surgery for oesophageal achalasia are comparable. Both approaches were able to strongly reduce preoperative LES basal pressure with a similar incidence of postoperative pathological reflux at 24-hour pH-monitoring. The higher postoperative LES basal pressure and the lower TRT mean value after laparoscopic treatment could be explained by a much less mobilization of the gastro-oesophageal junction than in the traditional approach.

Preperitoneal laparoscopic hernia repair: totally extraperitoneal (TEP) or transabdominal (TAPP) approach?

X. Feliu, R. Clavería, E. Fernández-Sallent, P. Besora, E. Macarulla, J.M. Abad and J. Camps *Department of Surgery, Hospital General d'Igualada, P. Verdaguer 128, 08700 Igualada, Barcelona, Spain*

Aim: To evaluate our results in preperitoneal laparoscopic hernia repair with two techniques used: transabdominal approach (TAPP) vs totally extraperitoneal (TEP).

Material and methods: Since November 1993 to December 1997 163 laparoscopic hernioplasties have been performed in 125 patients. Thirty-eight of them had bilateral hernias and 27 (16·6 per cent) patients had recurrent hernias. The median age was 52·2 years (25–76). In 95 cases TAPP was the approach employed and TEP was used in 68.

Results: The median operative time in TAPP was 59·3 minutes (40–150 minutes) and 55·5 minutes in TEP, but the type of hernia, peritoneal tear and the learning curve has a significant influence in TEP's longer surgery time ($P<0.05$). Complications were reported in five TAPP (5·2 per cent) and four TEP (5·8 per cent); mainly local haematomas. Conversion was needed in three TAPP (3·1 per cent) for technical difficulties and seven TEP (10·1 per cent) due to peritoneal tears in six cases and haemorrhage in the other patient; open surgery was used in four cases and TAPP in the other three patients. There were five recurrences (3 per cent): three TAPP finished the learning curve (big direct hernias) and two TEP in the initial learning period of this procedure (missed hernia sac). Day surgery was used in 92·8 per cent of cases.

Conclusions: The results of laparoscopic hernioplasty are similar to open surgery, with painless and short postoperative recovery. We prefer TEP approach because is based in classic preperitoneal precepts. Although technically more difficult, it avoids the potential risk of damaging intra-abdominal organs, vasculary injury or pneumoperitoneum, and spinal anaesthesia can be used.

Colectomies for patients over 80 years old: prospective comparison with a younger population

H. Johanet, J.P. Cossa, D. Chosidow, J.P. Marmuse and G. Benhamou *Groupe Hospitalier Bichat-Claude Bernard, 46 Rue Henri Huchard, 75018 Paris, France*

The aim of laparoscopic approach is to speed recovery in the postoperative period. A prospective trial was conducted to assess the postoperative recovery after laparoscopic colectomies for patients over 80 years old (group A) and this population was compared with younger population (group B). All patients had a laparoscopic approach for colectomies except carcinoma Dukes A, B and C in group B. Eighty-six consecutive first patients were operated: 26 in group A (80 to 104 years old), 60 in group B (28 to 79 years old). The ASA score was 2·07 in group A (age criteria excluded) against 1·7 in group B (non-significant: NS for $P<0.05$). In group A, 10 patients were ASA 3 or 4 (nine in group B: NS). Indications were group A: 16 cancers, three sigmoidities, four polyps, two prolapses, one volvulus; for group B: 17 cancers, 25 sigmoidities, 15 polyps, two ischemias, one recto-vaginal fistula. Operative procedures were in group A, 15 sigmoidectomies, eight right colectomies, three for left angulus or transverse; in group B: 39 sigmoidectomies, 11 right colectomies, four for left angulus or transverse, six anterior resection or amputation of rectum. No significant difference was found between the two groups according length of resection (17·6 cm in group A against 16·08 cm in group B), conversion rate (23 against 15 per cent), length of procedures (137 minutes against 143 minutes), operative mortality (11·5 per cent against 6·6 per cent), surgical reintervention (3·8 against 15 per cent), the postoperative day for removal of nasogastric tube (3·3 against 3·11 days), day of postoperative recovery (not any tube or drainage: 7·88 days against 8·03 days), day of going home (14·3 days against 12·7 days). These results suggest that there is no age limit for laparoscopic approach for colectomies.

Laparoscopic adrenalectomy – standard treatment of the adrenal tumours

P. Kothaj, L. Laca, L. Marko, L. Sinkovič and P. Molnár
Department of Surgery, F.D. Roosevelt Hospital, 975 17 Banská Bystrica, Slovakia

Aim: Is laparoscopic adrenalectomy safe and effective procedure for adrenal tumours including tumours larger than 4 cm? How many trocars are necessary to perform safe laparoscopic adrenalectomy?

Materials and methods: Forty-one patients who underwent adrenalectomy for adrenal tumours during period 1992–1997. Twenty-five conventional adrenalectomies, nine laparoscopic adrenalectomies in initial period using five trocars (only tumours smaller than 4 cm), seven laparoscopic adrenalectomies in advanced period using three (or four) trocars (also tumours larger than 4 cm). Comparison of mortality, morbidity, time of operation, rate of conversion and hospital stay between three periods of adrenal surgery: conventional, initial period of laparoscopic surgery, advanced laparoscopic surgery.

Results: Average duration of operation: conventional – 90 minutes, initial period of laparoscopy – 120 minutes, advanced period of laparoscopy – 80 minutes. Mortality: 4 per cent (one patient), 0 per cent, 0 per cent respectively. Morbidity: 8 per cent (two patients), 0 per cent, 0 per cent, respectively. Postoperative hospital stay: 9 days, 5 days, 3 days, respectively. Conversion: initial period – 22 per cent (two patients), advanced period – 0 per cent.

Conclusion: During the advanced period of laparoscopic adrenalectomy we proved that this procedure is safe and effective for also small adrenal tumours and tumours larger than 4 cm. It can be done safely using only three trocars in left-sided and four trocars in right-sided adrenalectomy.

Endoscopic papillotomy – when is surgical aid needed?

R. Markert, M. Gryszkiewicz, J. Wasiak and Z. Muras *Clinic of General Surgery and Transplantology, 90-153 Łódź, Kopcińskiego 22, Poland*

The ever-growing improvements in endoscopic techniques have made it possible to approach the common bile duct without surgical intervention, and thus have initiated a new stage in the treatment of the biliary tract and pancreas diseases. The aim of the study was assessment of papillotomy complications with a need for surgical aid. In the years 1987–1997, in the Endoscopic Laboratory (995) endoscopic papillotomies were performed: 647 in choledochal calcinosis, 148 in stenosis of the Vater's papilla, 66 in acute pancreatitis, 61 for exploratory purposes, and 73 in chronic pancreatitis. At that period of time 31 complications developed that required surgical intervention: acute pancreatitis in 21 cases, bleeding in two patients with indications for surgical aid and in seven treated conservatively, restenosis of papilla in six cases, and Dormia's basket impaction in two cases. Four patients in all died: three in the course of acute pancreatitis, and one from myocardial infarction. Diagnostic difficulties and criteria as well as the methods of surgical management in these patients are discussed.

The authors are of the opinion that endoscopic papillotomy constitutes a remarkable advance in the treatment of the biliary tract diseases, but that it should be done by highly skilled endoscopists cooperating with surgeons sensitized to the early diagnosis of possible complications and to their early effective surgical treatment.

Transanal endoscopic microsurgery (TEM): technical changes towards a one-surgeon procedure

*J.M. Ramirez, *V. Aguilella, *M.J. Palacios, *D. Arribas, *M. Martinez, *R. Lozano and †G. Buess **Servicio de Cirugia, Hospital Clinico Universitario, Zaragoza, Spain †MIC, Universitat klinik, Tübingen, Germany*

Aim: Technology which has been used in the operating room often with little regard to the cost, is emerging now as a help on providing quality care at lower cost. In fact, minimal invasive surgery is moving to the 'solo' surgery conception which would reduce hospital cost by both shortening surgical case time and increasing staff productivity. Transanal Endoscopic Microsurgery (TEM), a world-wide recognized technique for the local treatment of rectal tumours, was conceived as a two-people procedure mainly as a way for direct training. This paper presents the changes introduced to facilitate TEM as a one-surgeon technique.
Material and method: In January 1996 we started working on the one-surgeon TEM technique. First studies lead us to design a new suction device to be used with the right hand. The prototype was tested on laboratory pigs, performing both mucosectomy and full-thickness resection. These experiences served to develop the final version of the suction device as well as the concept to its use.
Results: The new catheter was clinically applied in July 1996. Since then, we have used it on 12 rectal tumours. Results regarding both operating time and blood lost were similar to those offered by the two surgeon technique.
Conclusions: Only minor changes were required to facilitate TEM to be performed just for one surgeon. In the competitive health care environment, we need to continue to explore new types of technology to help us maintain quality while lowering costs.

Gasless and CO_2 pneumoperitoneum laparoscopic surgery: a prospective and randomized study

J. Raposo D'Almeida, H. Vasconcelos Dias, J.L. Nunes, A. Menezes Silva, C. Balhana and M.J. Queiroz-Medeiros
Department of Surgery, Hospital de Pulido Valente, New University of Lisbon, Alameda das Linhas de Torres 117, 1750 Lisbon, Portugal

CO_2 pneumoperitoneum induces respiratory and haemodynamic changes which may be problematic for patients with high risk of developing cardiopulmonary complications. Gasless laparoscopic surgery would be an alternative route to avoid deleterious effects inherent to pneumoperitoneum. The purpose of this study was to compare perioperative and postoperative disturbances in patients who underwent laparoscopic cholecystectomy, gasless and under pneumoperitoneum.
Patients and methods: The effects of both procedures were studied in 60 patients undergoing laparoscopic cholecystectomy, who were randomly assigned in two groups: Group A – 30 patients in whom the operation was carried out under CO_2 pneumoperitoneum; and Group B – 30 patients undergoing gasless laparoscopic cholecystectomy. Mean operative time and mean blood loss were similar in both groups. Several parameters were registered preoperatively, perioperatively and postoperatively: pulse rate, arterial rate, arterial blood pressure, central venous pressure (CVP), arterial oxygen tension ($PaCO_2$), CO_2 arterial ($PaCO_2$), arterial pH, % O_2Sa and End-Tidal CO_2.
Results: We noticed significant decrease in pH values and pulse rate (postoperatively), increase in $PaCO_2$ and CVP (perioperatively), and increase in End-tidal CO_2 (perioperatively and postoperatively) in the group A, which were statistically significant ($P<0·05$).
Conclusions: As alterations under gasless laparoscopy are significantly fewer than after pneumoperitoneum they provide objective support for performing gasless approach in patients at high risk for developing cardiopulmonary complications, for whom CO_2 pneumoperitoneum may be a contra-indication.

Minilaparoscopy in abdominal malignancies

P. Spinelli, G. Di Felice, A. Schicchi, G. Calarco, B. Stefanon, M. Merola and M. Schiavo *National Cancer Institute, Via Venezian, 1-20133 Milan, Italy*

Current experience indicates that laparoscopy is an important tool for the evaluation of patients with malignant abdominal disease.
Materials and methods: In order to determine the reliability of minilaparoscopy for diagnosing, staging and restaging abdominal malignancies, 61 patients were evaluated using a 2 mm instrument (Auto Suture, USSC) in an endoscopy suite, under conscious sedation (5–10 mg of diazepam) and local anaesthesia (10–20 ml of mepivacaine 1 per cent). The procedure required the insertion of two small diameter trocar sites and only 1·0–2·0 l nitrous oxide to obtain adequate pneumoperitoneum.
Results: In 17 patients the procedure was performed with diagnostic purpose. Out of six women with a pelvic mass, ovarian cancer was diagnosed in five, and myoma in one. Among 11 patients with ascites of unknown origin we diagnosed a mesothelioma in five, an ovarian cancer in two, a pseudomyxoma in one, and metastases from breast cancer in three. In nine patients the procedure was performed to stage digestive tumours. Out of seven patients with gastric cancer, six revealed clinically evident ascites, and in one ascitic fluid was detected by endosonography. The remaining two patients with ascites were affected by HCC. In all patients minilaparoscopy demonstrated peritoneal spread. In 35 patients the procedure was performed to restage ovarian cancer. Positive macroscopic findings were confirmed by cyto-histological samples in 13 cases: in these patients serum marker level was normal. In 22 cases laparoscopy and cyto-histologic samples were negative: the serum marker level was normal in these patients too. Two of them were submitted to surgical removal of a retroperitoneal and a vaginal lesion, respectively: in these cases surgery confirmed the absence of endoperitoneal malignancy. Neither complications occurred, nor adhesions limited exploration of the abdominal cavity. In all cases, the discomfort was minimal during laparoscopic procedure, and absent in the following 24 hours. In this period after laparoscopy, no patient required analgesic drugs. With regard to impact on treatment, minilaparoscopy prevented surgical exploration in 54/61 patients and modified therapeutic approach in 16 cases (surgery → definitive or neo-adjuvant chemotherapy).
Conclusions: In our experience, minilaparoscopy seems to be a safe and reliable procedure for diagnosing, staging and restaging abdominal malignancies, with optical performance similar to that of conventional instruments, minimal, if any, discomfort for the patients and significant role in the management of oncological patients.

Laparoscopic treatment of hiatal hernia

J. Vazquez Echarri, J.M. Romeo, M.L. Ares and C. Montes
Hospital 'Severo Ochoa', Avda. de Orellana s/n 28911 Leganes, Madrid, Spain

Introduction: In our opinion the surgical treatment of the gastro-oesophageal reflux should be done nowadays by laparoscopy which permits the performance of the same operations and decreases the surgical trauma.

Patients and methods: During the last five years we have performed 92 laparoscopic operations for treatment of hiatal hernias. All of them presented with a long history of gastro-oesophageal reflux and upper gastrointestinal haemorrhage episodes with non-satisfactory response to medical and postural treatment. Eighty-seven patients had a moderate-severe oesophagitis (grade I-II in 50 cases, III in 19 cases, and IV in 18 cases), showed pathologic gastro-oesophageal reflux (mean % time pH<4·20, mean De Meester score 72·5, mean episodes over 5 minutes, nine) and low rate of LESP (mean 6·3 mmHg) according with their hiatal hernia. Average time of surgery was 134 minutes. One conversion to laparotomy (1 per cent) was necessary because of arterial bleeding. The surgical technique was always similar, using five ports. In all cases the hiatus was narrowed, calibrating with a 50 F oesophageal tube in 64; 89 Nissen-Rossetti fundoplications were performed in a length around 2·5–3 cm and two Dor fundoplications, one case because of motor oesophageal disorders that dissuaded us from a complete fundoplication and in the other because of technical troubles.

Results: Postoperative recoveries were uneventful (mean postoperation stay of 2·4 days). Forty-five cases complained of mild solid dysphagia that disappeared between 15 and 120 days. pH recordings and manometries made between two and four months after surgery in 54 cases showed no gastroesophageal reflux and high LESP (16 mmHg of mean). After 3 months 77 per cent of patients were asymptomatic, and after 1 year this rose to 91 per cent.

Conclusions: From our experience, we feel that the results are comparable to those obtained with the open technique, with a reduction in surgical sequelae.

Double-stapled anastomosis after anterior resection for rectal cancer

A. Amato, M. Mauro and A. Gramegna *Dipartimento di Gastroenterologia, Presidio Ospedaliero di Sanremo, Via Borea 56, 18038 Sanremo (IM), Italy*

Aim: A consecutive series of patients submitted to low anterior resection with double-stapled anastomosis below the pelvic peritoneum has been prospectively evaluated to identify the surgery-related risk factors influencing anastomotic complications.

Materials and methods: Between November 1994 and August 1997, 115 patients (60 men, 55 women) with a mean age of 69·3 years were operated on for rectal cancer. The site of lesion was the rectal-sigmoid junction in 41 patients, the upper rectum in 37 and the middle-lower rectum in 37. Preoperative radiotherapy and chemoradiotherapy was delivered in 11 and four cases respectively, with a mean radiation dose of 4000 Gy.

Splenic flexure mobilization, inferior mesenteric lymphoadenectomy and total mesorectal excision for extraperitoneal rectal cancer were routinely carried out. A protective colostomy was performed in 7/105 patients who underwent elective surgery and in 10 patients who had emergency surgery.

Results: Postoperative mortality was 3·5 per cent (four patients). A radiological leak was detected in three (2·6 per cent) patients, a clinical leakage was observed in three (2·6 per cent) patients with no leak-related death or peritonitis. Furthermore, one colovaginal fistula and one anastomotic haemorrhage were reported. Four (3·5 per cent) patients developed an anastomotic stricture, treated by serial mechanical dilatations.

The incidence of anastomotic complications was significantly increased when anastomotic height was less than 6 cm from the anal verge ($P<0·05$). Leak rate appeared directly related to the proximal extent of colonic resection ($P<0·05$). No significant relationship to age, sex, tumour stage, neo-adjuvant treatment, emergency or elective surgery was found.

Conclusions: Double-stapled technique is reliable and safe. Surgical risk factors include the proximal and distal extent of colorectal resection. This study suggests that a diverting stoma is rarely required.

The role of local excision for rectal cancer

A. Balani, A. Turoldo, A. Braini, M. Roseano and A. Leggeri *Istituto di Clinica Chirurgica Generale e Terapia Chirurgica, Ospedale di Cattinara, Strada di Fiume, Trieste, Italy*

The aim of this retrospective study was to evaluate the results of local excision (LE) for rectal cancer for curative purposes and to compare them with those achieved after abdominoperineal resection (APR) and sphyncter saving resection (SSR).

From 1969 to December 1997, a total of 456 operations were performed for surgical treatment of rectal carcinoma (262 males and 194 females, mean age 66 years). Twenty patients underwent LE, seven males and 13 females, median age 65 years. Patients were selected for LE if they met the following criteria during preoperative staging: tumours staged as T_1, N_0, M_0 with a distance from anal verge <10 cm, grading G_1 or G_2, size <3 cm, not ulcerated. Preoperative evaluation included a colonscopy with biopsy, transrectal ultrasonography, a barium enema and in some cases a pelvic TC. As far as the type of LE is concerned, we performed 13 transanal excisions (Francillon technique), two Mason, three endoscopic excisions and two TEM. In patients who underwent TEM the tumour was located at 8 and 10 cm from anal verge.

Among patients who underwent LE there was no operative mortality. Thirteen tumours were T_1 and seven were T_2: pathologic findings included 20 adenocarcinoma, 13 G_1 and seven G_2. There was no postoperative specific morbidity, while aspecific morbidity was minimal (5 per cent) including one pneumonia. There were no local recurrences but two patients (10 per cent) had secondary lesions. Five-year overall survival after LE was 88·4 per cent. Comparing T_1 and T_2 tumours after APR and SSR (17 T_1 and 44 T_2, all adenocarcinoma), operative mortality, specific and aspecific morbidity were respectively: 1·6 per cent ($P=0·56$), 19·6 per cent ($P=0·031$) and 11·7 per cent ($P=0·38$). There were five (8·3 per cent) local recurrences ($P=0·18$) and five (8·3 per cent) metastatic lesions ($P=0·81$). Five-year overall survival was nearly the same as LE (82·8 per cent with $P=0·63$).

LE for rectal carcinoma can be performed in selected patients provided there is correct preoperative staging. Five-year overall survival, local recurrence and operative mortality were similar to APR and SSR, while there was an improvement in results after LE in terms of specific morbidity.

Total mesorectal excision for the surgical treatment of rectal cancer

A. Bolognese, M. Cardi, I.A. Muttillo, R. Maira, L. Amadori and V. Arsena *I Istituto Clinica Chirurgica, Chirurgia Oncologica, Universitá di Roma, 'La Sapienza', 00161 Rome, Italy*

The aim of this study was to retrospectively evaluate the results of two groups of patients admitted and treated for rectal cancer in our Institution. From 1980 to 1992, 198 patients were admitted and operated for cancer of the rectum. Forty-seven were lost to follow-up and 151 patients were available for evaluation. The patients admitted and treated from 1980 to 1987 (80 patients, group A) were radically operated with standard technique, patients operated from 1988 to 1992 (71 patients, group B) underwent total mesorectal excision (TME). Mean follow-up was 73·5 months. Groups were similar according to demographics, staging and pathological data.

Results: No operative mortality was observed in this series. Complications were observed in 12 patients (15 per cent) in group A and in 23 patients (32 per cent) in group B. Local recurrences were found in 33 patients (41·2 per cent) in group A and in nine (12·6 per cent) in group B. Distant metastases occurred in 17 (21·2 per cent) and in five (7·6 per cent) respectively in groups A and B. Cancer-related mortality was 62·5 per cent in the non-TME group and 19·5 per cent in TME group. Overall 5-year survival was 32·4 per cent in group A and 70·5 per cent in group B. Disease-free survival was 25 per cent and 62·3 per cent in group A and B respectively. From the results of our study, it can be concluded that TME seems to lower the incidence of cancer-related mortality, with a higher incidence of postoperative complications. Further studies need to be done to assess the real benefits of TME in the surgical treatment of rectal cancer.

Emergency presentation of colorectal malignancies: experience of an emergency surgery unit

O. Campione, M. Vivarelli, N. Marrano, E. Pasqualini, G. Caló and G. Orazi *Divisione di Chirurgica d'Urgenza, Dir. Prof. O. Campione, Policlinico S. Orsola-Malpighi, Dipartimento di Scienze Chirurgiche e Anestesiologiche, Universitá di Bologna, Italy*

To assess the incidence of large bowel cancer as a casue of abdominal surgical emergency, our series of 2745 consecutive patients referred to the Emergency Surgery Unit of the University Hospital over a 2-year period (October 1995–October 1997) was retrospectively reviewed. The Unit collects patients from a population area of about 200 000 people. Only those patients were considered who had non-traumatic abdominal emergencies. Two hundred and one patients were admitted for an acute presentation of a large bowel disease, 125 of them had cancer; there were 67 males and 58 females, mean age was 71·5 (SD: 11·11). Presentation of the neoplastic disease was with intestinal obstruction in 68 cases, peritonitis due to colonic perforation in 10, rectal bleeding in 25, acute abdominal pain in 21 and vesicoenteric fistula in one. The tumours were more frequently located in the sigmoid colon (35 cases) and the rectum (34), while caecum and descending colon were the least common sites (respectively 14 and nine cases). One hundred and twenty three emergency procedures were carried out on these patients, as two of them died before surgery. The tumours were mainly advanced (Dukes C: 118 cases; Dukes B: three cases; Dukes A: four cases) with seven cases of diffuse periotoneal cancer implantation, and five of infiltration of other organs. Colonic resection was performed on 106 patients while 17 patients had intestinal by-pass procedures or colostomy becasue of too advanced disease or poor general conditions. Operative mortality was observed in four cases (3·2 per cent). Thus, large bowel tumours were responsible for 4·5 per cent of all the abdominal emergencies; they also accounted for 35·4 per cent of all intestinal obstructions, 10·8 per cent of peritonitis and 55·5 per cent of rectal bleeding episodes observed during two years of activity.

Whereas great emphasis is posed on the early diagnosis of colorectal malignancies, they still represent a common indication for emergency surgery. These data confirm the need of a more intensive surveillance, particularly in older people, on early symptoms of large bowel cancer.

Implementation of a policy of preoperative radiation therapy and total mesorectal excision in rectal cancer treatment

W. Ceelen, A. Cardon, P. Pattyn, U.J. Hesse, *M. De Vos, †W. De Neve, ‡S. Van Belle and B. de Hemptinne *Deparments of Surgery, *Gastroenterology, †Radiotherapy and ‡Oncology, University Hospital Ghent, De Pintelaan 185, 9000 Ghent, Belgium*

Introduction: Surgical treatment of rectal adenocarcinoma is followed by local recurrence in as much as 30 per cent of patients, resulting in significant morbidity. Recently, preoperative radiation therapy (RT) has been shown to improve local recurrence rates as well as long-term survival. We prospectively evaluated the value of preoperative RT followed by total mesorectal excision (TME), which is considered to be the current standard in rectal cancer surgery.

Patients and methods: Thirty-one patients were treated in a four-year period. Mean age was 60 (range 56–65); 19 (61 per cent) were male. Seventeen (55 per cent) patients had a low tumour (0–5 cm). All patients underwent short-term hyperfractionated RT (total dose: 41·6 Gy) immediately followed by surgery. Sphincter-preserving surgery was performed in 19 (61 per cent) patients. Mean follow-up was 23 months.

Results: UICC Stage distribution was as follows: Stage O: one (4 per cent); Stage I: 10 (32 per cent); Stage II: eight (26 per cent); Stage III: 10 (32 per cent); Stage IV: two (6 per cent); two patients had R2 resections (liver metasases). There was no in-hospital mortality. RT was reasonably well tolerated by most patients; five patients (16 per cent) developed serious side-effects: rectovaginal fistula (2); radiation colitis (2) and subobstruction by adhesions (1). No anastomotic leaks were seen. Mean overall survival was 39 months; Kaplan–Meier analysis resulted in survival after one and three years of 91 per cent and 79 per cent respectively for R0 resections. Local recurrence developed in two (6 per cent) and isolated distant recurrence in two (6 per cent) patients operated on with curative intent.

Conclusion: The combination of preoperative RT and total mesorectal excision resulted in excellent figures for local recurrence rate and intermediate-term survival; long-term follow-up is needed to confirm our present findings. Toxicity of the RT regimen remains worrysome, but will probably diminish with increasing technical expertise.

Prognostic value of DNA ploidy in patients with B and C Dukes colorectal carcinoma

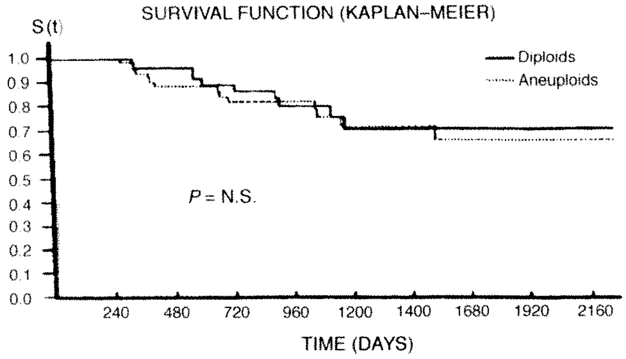
J. Garcia Garcia, A. Bellido Luque, J. Ciudad Pizarro, A. Lopez, F. Cuadrado Idoyaga, A. Orfao Matos and A. Gomez Alonso
Dpto de Cirugia, Servicio de Citometria, Hospital Universitario, Paseo S Vicente s/n, 37007 Salamanca, Spain

Aim: To determine the value of DNA ploidy in the prediction of recurrence in colorectal carcinomas.

Patients and methods: Curative resection was performed in 123 unselected patients with B and C Dukes colorectal carcinomas. Flow cytometry of DNA (CF) was performed in fresh specimens at time of resection. Patients were followed until the end of 1996 when the present study was closed. Recurrence was analysed by Cox's proportional hazard regression model. The presentation of recurrence was considered the event and follow-up was defined as time elapsed between intervention and last revision or the presentation of recurrence. Significance was performed by log rank test.

Results: Twenty-five recurrences were detected (16 in rectal cancer and eight in colon cancer). Seventy-one carcinomas (58 per cent) were found to be aneuploid and 52 diploid. Neither ploidy nor data of cell cycle (G_0/G_1, S and G_2/M) were found to be significantly correlated with the recurrence.

Conclusions: No flow cytometry data could significantly improve the prediction of recurrence.



Lack of genetically detected circulating tumour cells render the 'no-touch isolation technique' unnecessary in colorectal cancer

D. García-Olmo, J. Ontañón, D.C. García-Olmo, *M. Vallejo and J. Cifuentes *Experimental Research Unit and Department of General Surgery, Albacete General Hospital, Albacete, Spain*
**Reproductive Endocrine Unit, Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA*

Aim: The benefits of the 'no-touch isolation technique' usually carried ou to prevent the circulation of tumour cells are not evident. The aim of thi study was to determine whether conventional surgical procedures fo treatment of colon cancer could provoke the circulation of tumour cell detected by a genetic technology.

Methods: Fifteen patients undergoing resection for colorectal cancer an two patients with irresectable tumour were studied. No patient showe liver or lung metastasis. With specific primers for carcynoembryonic antigen (CEA), we used the reverse transcriptase-polymerase chain reactio (RT–PCR) to analyse tumour biopsy specimens and blood sample obtained from the antecubital vein prior to and after surgery and from th main drainage vein of the tumour when the tumour was being extracted Peritoneal fluid was also collected in irresectable cases.

Results: Amplification of cDNA with the primers specific for CEA specific primers was achieved with all tumour biopsies and samples o peritoneal fluid. In two patients CEA RT–PCR products were detected i antecubital vein prior to surgery and in one of them also after surgery Only in one patient (Dukes C) CEA RT–PCR products were detecte from the main drainage vein of the tumour. In serial dilution experiments we determined that limit of detection of this method was 10 tumour cell in 2 ml of blood.

Conclusion: Our results indicate that in the vast majority of patients les than 10 viable tumour cells are present in 2 ml of blood before surgery and that this number does not increase by performing standard surgica procedures to remove colorectal tumours. According to the no-touch isolation theory, this is the time when the probability of the tumour cell spread should be maximal. Our data suggest that the use of 'no-touc isolation techniques' in colorectal cancer is not justified, based on lack o evidence indicating the detachment of cells from the tumour upo surgery.

Results of endoscopic ultrasonography in preoperative detection of nodal metastases from rectal cancer

P. Spinelli, M. Schiavo, S. Andreola, E. Leo, F. Belli, G. Gallino and G. Di Felice *National Cancer Institute, Via Venezian 1, 20133 Milan, Italy*

Preoperative staging of rectal cancer is crucial to assess an appropriate therapeutic approach. Among all imaging modalities, endoscopic ultrasonography (EUS) is commonly considered as an accurate method of assessing tumour infiltration and lymph-node involvement. Perirectal metastastic lymph-node can be identified with reported sensitivity and specificity of approximately 80 per cent[1]. Recently it has been shown[2] that even the manual dissection instead of the clearing technique of the mesorectum can demonstrate metastases in approximately 50 per cent of the lymph-nodes smaller than 5 mm. Aim of this study was to analyse our experience with EUS in rectal cancer, relating our results to the technique used for pathological detection of lymph-nodes.

Materials and methods: From April 1991 to December 1997, 146 patients with rectal cancer, undergoing curative surgery without radiotherapy, were staged preoperatively by means of EUS. Endosonography was performed using Olympus GF-UM3/UM20 and CF-UM20 mechanical radial scanning echoendoscopes (frequency 7·5/12 or 7·5 MHz, scanning angle 360 or 300°). Seventy-eight specimens were examined by different pathologists with different experience, 68 by the same pathologist with particular interest in this disease. Statistical analysis was performed using the z-test, at the 5 per cent significance level ($z>1{\cdot}96$).

Results: Diagnostic accuracy of EUS for nodal staging significantly decreased according to pathological technique and incidence of metastases in lymph-nodes <5 mm. The results for the two groups of patients were the following: overall accuracy (78·2 per cent vs 47·1 per cent [$z=3{\cdot}98$]), sensitivity (70·9 per cent vs 27·7 per cent [$z=3{\cdot}52$]), specificity (79·6 per cent vs 68·7 per cent [$z=1{\cdot}14$]), positive predictive value (68·7 per cent vs 50·0 per cent [$z=1{\cdot}37$] and negative predictive value (81·2 per cent vs 45·8 per cent [$z=5{\cdot}31$]).

Conclusions: Although EUS is a reliable and highly accurate method for preoperative nodal staging of rectal cancer, the results are related to the technique used by the pathologist when dissecting the surgical specimen.

Virtual colonoscopy in the diagnosis and staging of colorectal neoplasms

Z. Tarján and *Zs. Eles *Department of Radiology and *1st Department of Surgery, Semmelweis Medical University, Ulloi ut 78/a, 1082 Budapest, Hungary*

Aim: The purpose of this work is to demonstrate the level of detail and diagnostic possibilities of three-dimensional CT of the colon in patients with colorectal tumours and to compare the results with barium enema, fibreoptic endoscopy and operative results.

Materials and methods: Thirty-six patients (47–78 years, 16 female, 20 male) with suspected colorectal tumours underwent 3D CT colonography, fibreoptic endoscopy and double contrast barium enema examinations. The examinations were performed within a 3-day period. For 3D CT colonography, the colon after cleaning was retrogradely insufflated with air and iv. peristalticolyticum was given. A 45 second spiral, thin collimation scanning was performed during breathhold. A second spiral scan was added at the region of interest with i.v. contrast material. From these data 3D images and virtual colonoscopy simulations were generated on a separate graphic workstation. Views from outside, from inside, surgically opened views and holographic views were produced for preoperative assessment. The results were compared with those of fibreoptic colonoscopy, barium enema and biopsy.

Results: Virtual colonoscopy detected all 17 malignancies diagnosed by colonoscopy. Two additional higher tumours were diagnosed by virtual colonoscopy (and barium enema) not reached by partial colonoscopy. In detecting polyps, CT colonography was 100 per cent sensitive for polyps >20 mm, but only 60 per cent sensitive for polyps <20 mm. On CT scans used for virtual colonoscopy generation, the transmural extent and lymph node involvement of the tumour was well evaluable.

Conclusions: Virtual colonoscopy minimizes patient discomfort and inconvenience and seems to be a useful diagnostic modality in detecting and staging colorectal neoplasms. In virtual colonoscopy the right side of the colon can always be reached. For screening purposes technical refinements are needed to increase sensitivity for small polyps.

Laparoscopic transabdominal preperitoneal (TAPP) technique in the treatment of groin hernias

J. Bátorfi, O. Kelemen, G. Pósfai, É. Simon and A. Petöházi *General Surgical Department, County Legal City Hospital, Nagykanizsa, Szekeres u. 2-8, Hungary, H-8800*

There are several techniques for laparoscopic repair of inguinal hernias. Only two of these spread in the clinical practice; implantation of a mesh through transabdominal preperitoneal and total preperitoneal way, all of the others did not become generally used operation because of their complications and unacceptably high recurrence rate. In two departments 200 laparoscopic hernia repair have been performed at 165 patients by TAPP technique for three and a half years. Thirty-three patients (21·2 per cent=35/165) had bilateral hernias, and the indication of surgery was recurrent hernia after traditional herniorraphy in 67 cases (=33·5 per cent). Femoral hernias were operated on at three female patients. There were no intraoperative complications except damage to epigastric vessels in two cases which were easily managed through laparoscopy. Postoperative complications included three (1·5 per cent) hydroceles, nine (4·5 per cent) spontaneously resolving neuralgia and one (0·5 per cent) umbilical trocar hernia. All of the seven (3·5 per cent) recurrent hernias were developed during the first (1–4 months) after surgery, and were able to be explained with the lack of skill. There was only one recurrence from the last 100 cases. The advantages of the operations are the minimal postoperative pain, the lack of wound infections, early return to the normal activity (1–2 weeks after surgery) and in particular the more favourable conditions in the treatment of recurrent and bilateral hernias.

Calibrated inguinal hernioplasty with multiple plugs (variant of Trabucco repair)

A. Donati, G. Zanghì, G. Brancato, A. Privitera, E. Rinaldi and M. Donati *Cattedra di Chirurgia Generale I (Servizio di Chir. delle Ernie), Ospedale Vittorio Emanuele Via Plebiscito 628, 95123, Catania*

The authors propose to modify the Trabucco repair in the treatment of primary inguinal hernias, using one or more plugs and a standard double layer polypropylene mesh, fitting its hole to the variable distance of the funiculus from the pubic tubercle. From 1994 to 1997 the authors operated on 636 inguinal hernias distributed, according to Gilbert's classification modified by Rutwok and Robbins, as follows: I – 27 (4·2 per cent); II – 268 (42·1 per cent); III – 110 (17·3 per cent); IV – 06 (16·7 per cent); V – 3 (0·5 per cent); VI – 122 (19·2 per cent). A classic Trabucco repair was performed in 420 cases (66 per cent; in the remaining 216, two, three, four plugs were employed respectively (177, 38 and one case). Multiple plugs were used to reduce voluminous hernia sacs, suturing over them the disrupted fascia transversalis to the iliopubic tract. The calibrated repair was immediately assessed by stress test: 629 patients received local anaesthesia (98·9 per cent), three spinal (0·5 per cent) and only four narcosis (0·6 per cent). All the patients operated on under local anaesthesia ambulated immediately, had a meal shortly afterwards and were discharged within 24 hours. The following parameters have been used to value the method: hospital and domiciliary analgesic requirement (293 and 174 patients, 46 per cent and 27 per cent respectively), postoperative complications (10 patients, 1·6 per cent), driving cars and return to work of self-employed patients within five days (207 out of 248 and 76 out of 115 interviewed). During a 0 to 4-year follow-up, only one recurrence has occurred (0·16 per cent). The proposed technique permits a calibrated reconstruction of the posterior wall, with scanty pain, prompt functional rehabilitation and early return to unrestricted work.

Laparoscopic surgery for huge abdominal hernia: a series of 45 cases

G. Elhomsy, K. Varaei, W. Matta and B. Just *Centre Hospitalier de Troyes, Service de Chirurgie Digestive Troyes, France*

We report a retrospective analysis of 45 elderly and obese patients between 45–75 years who underwent laparoscopic cure of a huge ventral hernia between January 1994 and January 1997. This technique is perfectly adapted to elderly and obese patients. Complications are less frequent and better tolerated than for conventional open surgery. In this series, the success rate was 93·33 per cent with technique-related complications 5·5 per cent. None of the patients is dead. Three patients developed a later recurrence.

Prosthetic repair of incisional hernias

O. Yildirim, B. Koçer, M. Kiliç, F. Coskun, M. Karabeyoğlu, Ö.Cengiz, M. Koç, T. Ertan and G. Kiyak *Ankara Numune Hospital, Second Surgical Department, Ankara, Turkey*

In this retrospective study, evaluation of 161 cases of primary or incisional hernia operated by prosthetic repair and long term results of 60 cases were presented. In 74 patients mersilene mesh (Group I), in 74 patients prolene mesh (Group II) and in 13 patients steel mesh were applied. One hundred and forty-seven cases were postoperative ventral, primary umbilical or paraumbilical hernias and six cases were postoperative lumbar hernia. 'Strengthened primary repair' was applied in 153 cases. In eight patients the defect could not be closed primarily. In Group I, complication rate of early period was 17·5 per cent and that of late period was 4 per cent. The recurrence rate was 7 per cent and rejection rate was 6·7 per cent. In Group II complication rate of early period was 10·7 per cent and that of period was 2 per cent. The recurrence rate was 3·2 per cent and rejection rate was 2·7 per cent. Apart from surgical procedures used in recurrent hernias of abdominal wall, when indicated, prosthetic repair is especially useful in cases where tissues are not enough and repair is weak. As a result, we thought that in prosthetic materials, prolene mesh has an advantage over mersilene mesh.

Functional subfascial hernioplasty: a new technique in repairing groin hernias

M. González Penabad, M. López Bañeres, F.J. Rebollo López, A. Minguillón Serrano, J.J. Resa Bienzobas, J. Lagos Lizan and J.M. Del Val Gil *Department of General and Digestive Surgery, Obispo Polanco General Hospital, Teruel Av. Ruiz Jarabo 5, 44002 Teruel, Spain*

Aim: Many procedures have been described to repair groin hernias. The lowest rate of recurrences has been achieved with prostetic meshes. We have developed an alternative procedure for repairing inguinal hernias, using a polypropylene mesh, in retrofascial position, without opening the transversalis fascia and with anatomical reconstruction.

Material and methods: From January 1996 to June 1997, 39 patients with uncomplicated unilateral inguinal hernia were operated on. Local anaesthesia was used in nine cases, general anaesthesia in the other 30. According to the Gilbert–Rutkow classification the group included three type II patients, 15 type III, 21 type IV. One dose of Cefminox (2 g) was administered prior to the operation in all cases.

Anterior approach of the inguinal region. External oblique aponcurosis and cremaster muscle are cut longitudinally following their fibres. The sac is dissected, free of the cord elements, being replaced into the abdominal cavity when medium size and transsected when too large. Direct hernias are dissected and reduced through the internal ring. In none of the cases the transversalis fascia was open. Bogros space is completely shown. A possible femoral hernia is searched for. A polypropylene mesh (8 × 14 cm) is placed through the internal ring, behind the transversalis fascia, leaving a hole for the spermatic cord, like a brace. The most lateral point of the mesh is fastened to the muscular wall with a single non-absorbable stitch performing a Barker manouvre. Transversalis is folded with a continuous suture of non-absorbable material. Each cremaster muscle and external oblique aponeurosis are closed with a continuous absorbable suture.

All patients were followed up for an average time of 14 months (range 4–16).

Results: Haematoma occurred in one patient who was taking AAS. There was no incidence of wound infection, corditis, testicular atrophy or mesh intolerance. The discomfort level, according to an analogic score was mild (3/10). The postoperative recovery was excellent in the 39 cases. We did not find any instances of recurrent hernias.

Conclusions: This is a preliminary study, and more patients with a longer follow-up should be studied. We conclude that the functional retrofascial hernioplasty is useful in the reinforcement of inguinal canal floor, giving it back its dynamic qualities.

Comparative study between stoppa and laparoscopic repair in the treatment of bilateral inguinal hernia

P. Hauters, C. Lequeux, D. Meunier, S. Urgyan, A. Wittebole and A.M. Ruelle *Clinique Notre-Dame, 9 Avenue Delmée, 7500 Tournai, Belgium*

The study group consisted of 71 consecutive patients, presenting with bilateral hernia, operated on between 1993 and 1996. A Stoppa repair was performed on 37 patients (group S) and a transabdominal preperitoneal laparoscopic herniorrhaphy on 34 patients (group L). The series consisted of 65 men and six women, the median age was 56 years (range: 24–85). According to the Nyhus classification, there were 30 type 2, 77 type 3a, 23 type 3b and 12 type 4 hernias. Preoperative characteristics of both groups were equivalent. All the patients were evaluated in December 1997; the median follow-up was 33 months (range: 12–60). When comparing group S with group L, we noted a similar operative time: 103±24 vs 109±22 minutes (NS) but a longer postoperative hospital stay: 6±2 vs 4±1 days ($P<0{\cdot}001$). The postoperative pain was evaluated by a visual analogue scale (score from 0 to 10) and by the use of painkillers (g of paracetamol). On the first postoperative day, the two parameters were higher in group S; respectively 5·7±1·9 vs 4·7±1·4 ($P<0{\cdot}05$) and 1·7±1·7 vs 0·7±1·1 g ($P<0{\cdot}02$). That difference was no longer noted from the third postoperative day. Significant morbidity occurred in six patients of group S: two orchitis, two wound haematomas, one seroma, one pneumonia and in three patients of group L: one orchitis, one wound haematoma, one seroma (NS). We recorded a slower return to home activities in group S: 8±3 vs 6±2 days in group L ($P<0{\cdot}01$) but, the interruption of professional activities was similar in both groups: 30±10 vs 31±7 days (NS). Finally, we found two recurrences in group S and two in group L (NS). In conclusion, both procedures were associated with a low postoperative morbidity and hernia recurrence rate. We also recorded that laparoscopic herniorrhaphy was characterized by a lower postoperative pain. That advantage, even if limited to the first two postoperative days, induced a shorter hospital stay and a quicker return to current activities.

Recurrence of adult groin hernias five years after repair in a district general hospital

F.L. Hinson, J.W.F. Catto and R. Hall *Department of General Surgery, York District Hospital, York, UK*

Background: Little is known of recurrence rates for established methods of inguinal hernia repair in British surgical practice.

Methods: All groin hernias at York District Hospital in the year to 31st March 1992 were identified. Details of patient, hernia and repair were extracted from the casenotes. Recurrence was established by questionnaire, telephone and clinical examination for those who were unsure. Randomly selected patients who were certain that no recurrence had occurred were also invited to attend and 100 of these were examined.

Findings: We identified 554 patients and 604 groin hernia repairs. Seventy-seven notes were unobtainable; 30 patients (31 repairs) were uncontactable, leaving 496 repairs which were assessed for recurrence. Most were inpatient elective repairs of inguinal hernias under general anaesthesia. Fifty-seven repairs were for recurrent hernias. One hundred repairs were for bilateral hernias. Sutured repairs of various types were performed in most cases. The overall recurrence rate was 6 per cent (30 of 497 repairs). The recurrence rate for primary unilateral inguinal hernia was 2·9 per cent (10 of 342). The recurrence rate was significantly worse for recurrent hernias at 19·3 per cent (11 of 54) and for bilateral hernias at 9 per cent (9 of 100) for each groin. Recurrence rates were not significantly different for various methods of repair or for seniority of surgeon. A recurrent hernia was found in 6 per cent (6 of 100) patients randomly invited for examination after reporting no recurrence by questionnaire.

Conclusion: Various repairs give staisfactory recurrence rates for primary unilateral inguinal hernias. These methods are unsatisfactory for recurrent and bilateral hernias. Clinical examination is essential to establish true recurrence rates.

Has the mesh impact on wound healing after abdominal hernia repair?

Z. Máthé, D. Görög, Gy. Végsõ, F. Alföldy and F. Perner
Semmelweis Medical University Department of Transplantation and Surgery H-1082, Budapest, Baross u. 23, Hungary

Introduction: Incisional hernias are common complications following abdominal surgery. The use of prostheses is indispensable in major anterior abdominal hernias when it is not possible to close the edges of the hernial opening without tension. Despite the advantages of the synthetic meshes, complications after implantation are also reported.

Aim: To assess the incidence of early postoperative wound healing disorders and infections after elective abdominal hernia repairs with and without synthetic mesh implantation in the first four years of our Department.

Materials and methods: From January 1994 to January 1998 at our Institute 178 elective abdominal herniorapphies were performed. The inguinal hernias are not included in this study and the data were analysed retrospectively. Ninety-three incisional hernia repairs were done by preperitoneal technique using non-absorbable surgical mesh (first group). The male:female ratio was 20:73, average age 57 (28–78) years. In the second group (85 patients) conventional closure of the abdominal wall was chosen. The male:female ratio was 21:64, average age 54 (26–84) years. The body mass index (BMI) in the group I, was 34 kg/m^2 by males vs 32 kg/m^2 by females and 29 kg/m^2 vs 31 kg/m^2 in group II. Antibiotic prophylaxis (cephalosporin i.v., for 48 hours) and 48 hours bed rest was used at all patients with mesh implantation.

Results: Postoperative fever (over 38 grade C) occurred in 39 (42 per cent) in the first group vs 16 cases (19 per cent) in the second group. A significant difference was found in the length of surgery: mean operation time 123 minutes (45–240) in group I vs 60 minutes (15–210) in group II. During the early postoperative period (the first 30 days), in group I, wound healing disorders were detected in 11 cases (12 per cent). Eight of them (8·8 per cent) were seroma and necrosis of the skin margin and three of them (3·2 per cent) wound infections. In this group the rate of the diabetic patients was 8·6 per cent, and 37 per cent of them developed wound complications. The synthetic mesh has not required explanation in any case. In the second group there were no diabetic patients, one seroma (1·17 per cent) was found.

Conclusion: In overweight and diabetic patients with incisional hernias there is an increased risk of wound complications when mesh implantation is necessary, although the advantages of modern synthetic meshes are indisputable.

The continuing challenge of parastomal hernia – failure of a novel polypropylene mesh repair

G. Morris-Stiff and L.E. Hughes *Department of Surgery, University Hospital of Wales, Cardiff*

Aims: Parastomal hernia is a frequent complication of stoma formation which is seen following up to 50 per cent of colostomies and 10 per cent of ileostomies. Although there are many reports of successful repair techniques with excellent short term results, long term follow-up has been less satisfactory. Because of our own poor results with standard techniques, amply confirmed by others, we devised a novel technique, which we hoped might provide an effective barrier to the defect between the abdominal wall and the emerging bowel. We now report long-term results of the technique.

Patients and methods: In the period 1990–1992, seven patients were treated including five paraileostomal and two ileostomal hernias. The new technique involved constructing a fitted internal wrap using two pieces of polypropylene mesh. The meshes were cut to form three longitudinal 'fingers'. The outer 'fingers' were passed around the neck of the sac and overlapped to strengthen the abdominal wall around the defect. The middle 'fingers' were turned inward along the ileum/colon, and sewn together with polypropylene sutures to form a tubular sheath directed along the bowel into the peritoneal cavity for a distance of 3 cm. This sheath was loosely sutured to the seromuscular coat of the bowel, but was sufficiently loose to avoid constriction. The main bulk of each piece of mesh was sewn with interrupted polypropylene sutures to the parietal peritoneum and underlying muscle, ensuring coverage well beyond the margins of the defect.

Results: Five year follow-up has given disappointing results with recurrent hernia in two cases and serious complications including obstruction and dense adhesions to the intra-abdominal mesh in four and a mesh-related abscess in one case.

Conclusion: This study highlights a dual problem – failure of a carefully sutured mesh to maintain an occlusive position, and complications of the mesh itself. The poor results obtained with this technique together with the disappointing results of other methods confirms that parastomal hernia presents a continuing challenge.

Study of quality of life in relation with the health after the surgery of the endoscopic inguinal hernia vs conventional

J.M. Ramon, X. Carulla, J.M. Hidalgo, S. Navarro, M. Ferrer and J.M. Sánchez Ortega *Hospital Universitari del Mar de Barcelona, Pg. Marítim, 25-29 08003, Barcelona*

Aim: The analysis of the results about the surgery treatment of the hernias can not be limited to the determination of the morbidity and recidiva, but it must be included in the study of the quality parameters. Descriptive valoration of the life quality after the surgery of the endoscopic inguinal hernia vs conventional, taking use of two questionnaires of a health status measures and the analysis of the association between the declarate life quality and the different variables pre and perioperatories.

Materials and methods: Prospective and randomized study performed on 59 patients (53 men and six women) with a previous informed consent, in 31 was practised an endoscopic preperitoneal hernia-plasty (TEP) and in 28 an open hernia-plasty type Nyhus (O). All patients were operated on under regional anaesthesia. They registered filiation facts, type of work, level of studies, type of hernia, associated illness, etc. Also were filled up the pain levels and the mobility of two questionnaires of generic perceived health (SF-36 Health Survey and the Nottingham Health Profile NHP) before to the intervention and in the seven and 30 days of the postoperatory.

Results: The 56 per cent of the 59 patients of the study were working before the intervention and the 32 per cent returned to work at 30 days of the intervention, not existing significative differences between both groups. The average score of the two questionnaires administered correspond to a moderate global affectation to the perceived health after the intervention. The pain level of the NHP in the seven and 30 days of the intervention, with regard to the postoperatory, was bigger in the O (16 vs 4·6; P=0·08) and (15·4 vs 3·9; P=0·02) than in the TEP (12·6 vs 8·5; P=0·486) and (9·5 vs 8·9; P=0·9). The satisfaction level of the patients with both surgery techniques was 96 per cent.

Conclusions: The reduction of the secondary functional discapacity to the pain observed in the endoscopic group allowed the reduction of the hospital stay, the transitory work incapacity and will improve the quality of life of the sick people operated of inguineal hernia.

Randomized controlled double-blind trial to prove the effects of postoperatively applied local anaesthesia in reducing pain level in patients after tension-free inguinal hernia repair

S. Shah, R. Schmitz, M. Örder and J. Treckmann *Klinik für Allgemein-, Viszeral- und Unfallchirurgie, Evangelisches Krankenhaus Ferrenbergstr. 24, D-51465 Bergisch-Gladbach, Germany*

A prospective randomized double-blind study was performed on patients undergoing Tension Free Hernia Repair using the techniques of Lichtenstein. On the first postoperative day the patients were given either local anaesthesia (LA-group) or isotonic sodium solution (NaCl-group) through a drainage tube which was placed intraoperatively into the inguinal canal. The aim of the study was to evaluate a possible relief from pain in patients due to the postoperative use of local anaesthesia after Tension Free Hernia Repair.

Two groups, namely LA and NaCl, each consisting of 30 patients undewent Tension Free Hernia Repair. During the operation, which was performed under local anaesthesia, a drainage tube was placed beneath the aponeurotic layer of the external oblique muscle. On the first postoperative day the patients of the LA-group received local anaesthesia and the patients of the NaCl-group received isotonic sodium solution through the drainage tube, which was subsequently removed from the wound. The application of the solutions was performed in a double blind technique.

During a period of 6 days, from the operation day onwards, the perceived level of pain was measured with the help of a Visual Analogue Scale (VAS). All patients were mobilized early, latest 4 hours after the operation.

Comparing the pain sensation levels (VAS) between the two groups it could be observed that the patients of the LA-group experienced no significant advantage throughout the observation period.

This clinical trial demonstrated that the application of local anaesthesia 24 hours after Tension Free Hernia Repair does not significantly reduce the perceived level of pain in patients. This kind of analgesia is therefore not recommended as a postoperative analgesia after hernia repair.

Mesh prosthesis inguinal hernia repair: review of 492 consecutive cases

G. Vassallo, G. Meo, M. Rossetti, P. Geretto, C. Lauro, R. Rivetti and L.M. Quaranta *II Divisione di Chirurgia Generale, Azienda Ospedaliera S. Croce e Carle Via Michele Coppino, 12100 Cuneo, Italy*

Background: The use of a prosthetic material in repair of inguinal hernias is becoming common because it is less invasive and technically simpler and faster than traditional techniques and with a lower recurrence rate reported.

Material and methods: Our experience with 492 adult inguinal hernia mesh prosthesis repairs from 1993 to 1995 is reported. Lichtenstein's tension-free hernioplasty, and Trabucco's and Gilbert's sutureless techniques were used according to the personal choice of each surgeon of the team. The mesh was polypropylene, in a minority of cases PTFE Anaesthesia was general in 380 cases, spinal in 60 and local in 52. Two hundred and forty-eight patients have been followed up from 6 months to 2 years.

Results: Sixteen complications occurred for a rate of 6·4 per cent. There were five recurrences (2 per cent), three wound infections (1·2 per cent), four oedemas of external genitalia (1·60 per cent), four hematomas and ilioinguinal neuralgias (1·60 per cent). In two cases it was necessary to remove the mesh. There was no mortality and no venous thrombosis.

Conclusions: For the good results obtained, particularly the low recurrence rate compared with the traditional repair, we advocate the more extensive use of the prosthesis tension-free technique as the first choice procedure for all adult hernias, not only for recurrent, but also for primary or first-time hernias. The cost of the material is counterbalanced by lower need of postoperative analgesia, shorter hospitalization and a lower risk of recurrence. Nevertheless, we think that Bassini repair, nowadays the most widely used method, should be still included in the repertory of any general surgeon as the basic operative technique for inguinal hernia.

Pancreatogastrotomy after duodenopancreatectomy: analysis of 160 consecutive patients

J.P. Arnaud, J.J. Tuech, F. Navarro, Ch. Cervi, J.M. Fabre and J. Domergue *Department of Visceral Surgery, Angers, France. Department of Visceral Surgery, Montpellier, France*

Introduction: During the past 5 years, several papers exhibited a postoperative mortality of less than 8 per cent after pancreaticoduodenectomy, and no mortality in some skilled teams. Controversies exist about the advantages of the pancreato-gastrostomy over the classical pancreato-jejunostomy. In the present study the results of the pancreato-gastrostomy in 160 consecutive patients are assessed, and commented with special references to a collective review of the literature.
Patients and methods: From 1987 to 1996 all the patients referred to our department for a pancreatico-duodenal resection, underwent a pancreato-gastrostomy whatever age and status of the patient, the indication of the pancreatic resection and the texture of the remnant pancreas. There were 109 (68 per cent) males and 51 females (32 per cent). Mean age was 59±10 years (range 22 to 82), 27 patients were older than 70.
Results: In hospital mortality was 3 per cent (*n*=5). Overall morbidity was 30 per cent (*n*=49). Overall rate of pancreatic fistula was 2·5 per cent (*n*=4). Re-operation was required in 19 patients (12 per cent). Bleeding of the pancreatic section represented the main cause of re-operation complication (*n*=7). Delayed gastric emptying underwent in 22 per cent of patients (*n*=36). Mean hospital stay was 22 days ± 9, but was significantly longer in cases of delayed gastric emptying or pancreatic fistula.
Conclusion: Pancreatogastric anastomosis was feasible in all cases and yielded to a low mortality and morbidity rate. Others comparative prospective studies are mandatory to clearly define its place in the armamenterium of surgeons dealing with pancreatic resection. These studies should be reserved for expert centres with large volume of pancreatic resection, experienced surgeons, and a basic mortality and pancreatic fistula rate of less than 5 per cent.

Pancreatico-jejunostomy for chronic pancreatitis

F. Berrevoet, N. Van Heddeghem, M. De Vos, U. Hesse, P. Pattyn, R. Troisi, A. Elewaut and B. de Hemptinne
Department of Surgery, University Hospital, De Pintelaan 185, 9000 Ghent, Belgium

Drainage of the pancreatic duct in the treatment of chronic pancreatitis (CP) can be performed either surgically or endoscopically. Endoscopic drainage has been claimed to be associated with less morbidity and mortality, however long term results seem to be controversial.
Patients and methods: To assess our results of surgical treatment, 30 patients (M:F=26:4, mean age 42·6±13 years, range 25–80) who had undergone pancreatico-jejunostomy for CP were analysed. Aetiology of CP was alcohol abuse in 25 patients, biliary obstruction in three and idiopathic in two patients. Indication for surgery was persisting, severe abdominal pain. Surgical procedures included cysto-jejuno- or cysto-gastrostomy (10×), pancreatico-duodenectomy (4×), pancreatico-jejunostomy (12×), distal pancreatectomy (2×), subtotal pancreatectomy (2×).
Results: Postoperative complications occurred in four patients; mortality was 0 (the mean period of follow-up is 30 months, range 6–70 months). Immediate pain relief was seen in 96·6 per cent; only one patient complained of significant residual pain after surgery and could not discontinue his analgesic medication. Long term pain relief was complete in 47 per cent of the patients and partial in 50 per cent, in half of whom the pain related to recurrent alcohol intake. Ten patients had an abnormal OGTT of which seven needed increased doses of insulin after surgery. Nutritional status remained poor in six patients who did not gain weight after surgery. One patient needed a revision of the pancreatico-jejunostomy.
Conclusion: Pancreatico-jejunostomy is an efficient procedure resulting in pain relief in 93 per cent of the patients with total rehabilitation in 72 per cent. In patients with CP selected for a drainage procedure, surgery is a safe and reliable therapy.

Immediate and long term results of pancreaticojejunostomy in chronic pancreatitis

C. Casa, Ch. Cervi, J.J. Tuech, P. Lada and J.P. Arnaud *CHU Angers, Department of Visceral Surgery, Angers 49100, France*

Aim: To evaluate the results of pancreatico-jejunostomy in the treatment of chronic pancreatitis.
Patients and methods: From 1978 to 1995, 120 patients (105 males, 15 females with a mean age of 46 years) underwent pancreatico-jejunostomy (PJ) for chronic pancreatitis (CP). Alcohol abuse was presented in 105 cases (87·5 per cent). PJ was the unique procedure in 67 cases; it was associated with a biliary or a duodenal diversion in 38 cases and five cases respectively. In 10 cases, three diversions were performed.
Results: Postoperative mortality was 1·6 per cent (*n*=2), postoperative morbidity was 10 per cent (*n*=12). Mean hospital stay was 16 days (8–25 days). Fifteen patients (13 per cent) required a second operation some years subsequent to the PJ due to the progress of the CP or alcohol abuse. In the late postoperative course 22 deaths occurred (18 per cent), eight of them were directly related to alcohol abuse. Mean follow-up was seven years. Good and medium results for pain were achieved in 92 per cent of patients, but the progression of exocrine or endocrine pancreatic insufficiency indicated that wirsung decompression was insufficient to stop the progressive sclerosis.
Conclusions: Our results suggested that PJ was the best surgical procedure in CP treatment, when the wirsung was dilated.

Double loop reconstruction in Roux-en-Y mode after pancreaticoduodenectomy: a way to decrease postoperative morbidity and mortality?

N.A. Kama, T. Coskun, M. Doganay, E. Reis, A. Yazgan, G. Daglar and Y.N. Yuksek *Ankara Numune Hospital, 4th Department of Surgery, Turkey*

Aim: Pancreaticoduodenectomy (PD) continues to be associated with a high postoperative morbidity despite the improvement in operative technique and perioperative care. The use of two separate intestinal loops for anastomosis of the biliary tract and pancreas may decrease the rate of postoperative morbidity. The purpose of this study was to determine the incidence and cause of significant complications, and death following PD and compare double loop reconstruction after PD with standard reconstruction.
Patients and method: Between 1991 and 1997, 23 patients underwent PD because of periampullary neoplasm in 19 patients, recurrence after the local resection (ampullectomy) for ampullary tumour in one patient, duodenal invasion of the right colon tumour in two patients and choledochal cyst in one patient. Of the 23 patients, 14 were male and nine were female, with a median age of 52 years (range 26–72 years). Of the 23 patients, 10 (43 per cent) had undergone previous laparotomy in various centres: right hemicolectomy for colon carcinoma in two, cholecystectomy and T-tube drainage in two, cholecystectomy and choledochoduodenostomy in two, ampullectomy for ampullary tumour in one, gastrotomy for biopsy and gastrojejunostomy in one, gastronomy for biopsy in one and exploratory laparotomy for choledochal cyst in one patient. Ten patients underwent standard Whipple's procedure, nine pylorus-preserving PD and four PD with double loop reconstruction in Roux-en-Y mode (one jejunal segment for reconstruction of biliary tract and duodenal anastomoses and another for reconstruction of pancreatic anastomosis). The pancreatic remnant was anastomosed to the jejunum with an intussuspecting end-to-end anastomosis in all patients. All procedures were performed by the same surgeon.
Results: One or more significant complications prolonging hospitalization or resulting in a postoperative death occurred in six (26 per cent) patients. A single complication, pancreatic leak, developed in two patients, while four patients had two or more complications (leak in pancreatic and biliary tract anastomoses and pancreatic necrosis in one patient, leak in all anastomoses in one patient, leak in pancreatic anastomosis and intra-abdominal haemorrhage in two patients). Anastomotic leak from the pan-

creaticojejunostomy was the cause of all other complications and significantly associated with postoperative morbidity in this series (P=0·002). Three patients underwent reoperation for complications (re-pancreaticojejunostomy and control of bleeding in two patients and re-pancreaticojejunostomy in one patient). Of these patients only one survived reoperation. The overall postoperative mortality in this series was 17 per cent (n=4). There was no complication and mortality in the patient who underwent double loop reconstruction in Roux-en-Y mode. Although the patients with double loop reconstruction had shortened hospitalization (14 days vs 20 days) and operative time (380 minutes vs 420 minutes), this difference did not reach statistical significance (P<0·05).
Conclusion: The results of this study have shown that postoperative morbidity and mortality was significantly associated with the dehiscence of the pancreaticojejunostomy anastomosis. Two separate intestinal loops for anastomosis of the biliary tract and pancreas could be used to decrease the rate of postoperative morbidity and mortality.

Single layer continuous sutured anastomosis technique in pancreato-biliary surgery

A. Oláh, T. Belágyi and G. Pardavi *Department of Surgery, Petz A. County Hospital, Győr, Hungary*

Authors evaluated the safety of anastomosis performed with absorbable single layer continuous sutures in various surgical procedures in pancreatic and biliary surgery. In the prospective, non-randomized study 156 anastomoses were performed on 92 patients during the last two years. All procedures – including Whipple and pylorus-preserving pancreatoduodenectomy (PPPD), duodenum-preserving resection, longitudinal pancreatico-jejunostomy or -gastrostomy and biliodigestive anastomoses in case of irresectable pancreatic tumour or chronic pancreatitis – were carried out by the same surgeon. In all cases they used size 3/0 or 4/0 polyglecaprone 25 (Monocryl, Johnson and Johnson) or glycomer 631 (Biosyn, USSC) with single layer, running stitches.

The types of anastomoses: 26 longitudinal pancreatic anastomoses (17 Wirsungo-gastrostomy and nine Wirsungo-jejunostomy), 43 biliodigestive anastomoses (mainly choledocho-jejunostomy sec Roux) and 87 small intestine anastomoses (duodeno-jejunostomy end to end in the case of PPPD or jejuno-jejunostomy in the case of Roux-Y loop). Two minor biliary leakages were detected after bilio-digestive anastomoses. There were no leakage after longitudinal pancreatic anastomoses or duodeno-jejunostomy. No patient required reoperation for anastomosis related complication. Three patients died – but the complications were not connected with the suture technique.

The authors' opinion is that the described method is safe, easy to carry out, physiological and least harmful to the blood supply, so they recommend its use in pancreato-biliary surgery.

Failure of CT scan and ERCP in detecting proximal pancreatic and peri-pancreatic diseases

M.H. Shiwani, S. Anwar, D. Breen, T. Giles, R. Hodson and K.R. Wedgwood *Castle Hill Hospital, Castle Road, Cottingham, East Yorkshire, UK*

Aim: To analyse the findings of CT scan and ERCP for small volume proximal pancreatic and peri-pancreatic disease.
Materials and methods: Twenty-eight proximal pancreatic resections have been carried out in the last 3 years. Twenty-seven patients have undergone high resolution conventional or spiral CT scan (5 mm and 4 mm collimation respectively). All resected specimens underwent serial sectioning to demonstrate small volume disease. Twenty-five pateints also had ERCP.
Results: Final diagnoses of these 28 patients comprise 10 benign lesions (three acute pancreatitis, two chronic pancreatitis, one sclerosing cholangitis, two mucinous cystadenoma, one adenomatous hyperplasia and one villous adenoma) and 18 malignant lesions (10 adenocarcinoma of head of pancreas, three cholangiocarcinoma, three ampullary carcinoma, one carcinoid and one carcinoma of gallbladder). CT scan identified 13 lesions of which four suspected benign lesions were confirmed histologically. Of nine suspected malignant lesions only five were confirmed histologically and four were benign. In nine patients CT scan failed to identify a lesion but subsequent histology confirmed seven malignant and two benign lesions. All the five equivocal lesions on CT scan were malignant. ERCP cannulation failed in two cases (carcinoid and cyst adenoma), one ruptured pancreatic duct diagnosed secondary to acute pancreatitis. In three cases ERCP was normal, histology revealed two adenocarcinoma head of pancreas and one chronic pancreatitis. ERCP suspected 18 malignant lesions, histology confirmed 13, but five were benign.
Conclusion: Where clinical suspicion remains, a pancreatic resection should be seriously considered, even in the face of negative or equivocal CT scan or suspicious ERCP.

Restorative proctectomy with coloanal J pouch for obstructed defecation – an early appraisal

F. Abbasakoor, B. Patel and N.D. Carr *Department of Surgery, Singleton Hospital, Sketty, Swansea, UK*

Aim: Impaired rectal evacuation remains a challenging clinical problem. A variety of surgical options such as correction of anatomical abnormalities (if present), ACE (antegrade colonic enema) procedures and colostomy have been tried, but have met with limited success. The present study evaluates the use of proctectomy with coloanal pouch anastomosis in patients with intractable difficulties in rectal evacuation.
Materials and methods: Nine patients (eight females; 1 male; median age 44 years, range 34 to 63 years) underwent proctectomy with coloanal pouch anastomosis. Preoperative evacuation proctography was undertaken in all patients and findings included rectorectal intussusception (n=5), rectocele (n=6) and pelvic floor descent (n=4). In seven of the nine patients, delayed or incomplete evacuation was observed radiologically. Endoanal ultrasonography revealed co-existent sphincter defects in three patients and four patients had abnormal rectal compliance on anorectal physiology.
Results: Restorative proctectomy with stapled coloanal **J** pouch anastomosis was performed in all patients. A temporary loop ileostomy was constructed in two of these and both have been reversed. There were no perioperative complications. At a medium follow-up of 6 months (range 1·5 to 12 months), all patients report a subjective improvement in rectal emptying. The median frequency of bowel evacuation is three (range two to five) times daily. All remain continent of flatus and faeces.
Conclusions: The results of this preliminary study indicate that restorative proctectomy with coloanal pouch may have a role in the surgical management of patients with intractable difficulties in rectal evacuation.

Distal intramural spread of rectal carcinomas

A. Balani, A. Turoldo, C. Tonello, M. Scaramucci and A. Leggeri
Istituto di Clinica Chirurgica Generale e Terapia Chirurgica, Ospedale di Cattinara, Strada di Fiume, Trieste, Italy

The aim of the study is to examine distal rectal spread of rectal cancer and to determine the optimal distal margin of resection after sphincter saving resection (SSR).

At the Institute of Clinica Chirurgica of the University of Trieste 438 operations for rectal cancer were performed, 314 of which were for curative purposes.

The choice of the type of operation was related only to the location of the tumour; neither the stage, nor other risk factors were considered. To this purpose 220 SSR were performed. In 50 selected of these cases, distal intramural spread was detected. Surgical specimens were pinned under tension onto a wooden board and, below the distal edge of the tumour, a number of full thickness sections of 1 cm were performed.

In two cases a tumoral distal spread at 1 cm was observed, whilst an involvement beyond 2 cm was never demonstrated. The two cases with distal spread at 1 cm were advanced cancer with a full thickness infiltration, without nodal involvement; these patients were classified as G_2, one was aneuploidy and both had a high proliferation index.

The authors conclude that in the surgical treatment of rectal cancer, SSR is justified, provided a distal margin of 2 cm is respected. Even in advanced cancers a distal spread of over 2 cm has never been observed.

Laparoscopic-assisted colonic resection for diverticulitis: prospective study in 50 patients

J.L. Bouillot, K. Aouad, B. Alamowitch, P. Sellam, J. Fourmestraux and J.P. Bethoux *Department of Digestive Surgery, Hôtel Dieu, 1 Place Parvis Notre Dame, 75004 Paris, France*

Aim: To evaluate the feasibility, the safety and the results of laparoscopic-assisted colonic resection for diverticulitis.
Materials and methods: The surgical technique was a laparoscopically-assisted procedure: under laparoscopy, total mobilization of the left colon and vascular ligation were performed and then via a small abdominal incision (8 cm length), division of the colon, removal of the specimen and hand-sewn anastomosis. This approach was prospectively used in 50 consecutive patients (23 males, 27 females with a mean age of 62 years). The delay of surgery after the last acute attack of diverticulitis varied from one to four months.
Results: The surgical goal was achieved in 46 cases. In four cases (8 per cent), the laparoscopic dissection was unsuccessful and the procedure was converted via a large midline incision. The mean operative time was 195 minutes (150–280). There was no mortality and the morbidity rate was 14 per cent. No complication was directly related to the laparoscopic technique. The mean return of regular bowel habits was 3·2 days and the median postoperative stay was 10 days (6–22).
Conclusion: These preliminary results suggest that the laparoscopic-assisted sigmoidectomy can be used safely for the surgical treatment of diverticular disease. This approach seems to be technically easier and cheaper than the totally laparoscopic approach but reduces the expected advantages of minimal invasive surgery.

First 100 operations with MASA-2 anastomotic device in low anterior resection

M. Csiky, K. Noskó, S. Gál, S. Bakos, I. Markó, Z. Kruppa and P. Acosta *Department of Surgery, County Teaching Hospital Salgótarján, Füleki Street 64, Hungary, 3100*

The authors present their experiences in the first 100 operations practised for rectal cancer localized in the middle and lower third of the rectum with an anastomotic device developed by one of them. There were 61 men and 39 women between 36 and 78 years. Fifty-eight patients received preoperative radiotherapy (30 Gy), at 40 patients they applied total mesorectal excision.
Results: Spontaneous discharge of the anastomotic device was after nine days on average (range 6–14 days). Anastomotic dehiscence developed in 20 patients (20 per cent). Four patients died within 30 days. For all patients with total mesorectal excision the authors recommend a covering loop colostomy.
Conclusions: 1) The anastomotic apparatus is suitable to practise an air and watertight low colorectal anastomosis where this was not guaranteed by manual techniques. 2) After spontaneous discharge of the device foreign material does not remain in the tissues. 3) Its application necessitates a special technique. 4) Owing to the equal circular compression around the whole rim of the gut, bleeding does not occur. 5) In cases of total mesorectal excision a loop colostomy is recommended. 6) It is less expensive.

Relevant points to consider for selection of patients with peritoneal carcinomatosis for cytoreductive surgery and IP chemotherapy

A. Gomez Portilla, C. Martinez de Lecea, M. Stevens and P.H. Sugarbaker *Hospital Clinico Valencia, Spain*
The Washington Cancer Institute, USA

Aim: In an attempt to improve knowledge of the methodologies and relevant points to consider in order to the selection of patients with peritoneal carcinomatosis from colon and rectal cancer for treatment with cytoreductive surgery and intraperitoneal chemotherapy.
Material and methods: A group of 86 patients with biopsy proven peritoneal carcinomatosis from colon and rectal cancer, treated with cytoreductive surgery and early postoperative intraperitoneal chemotherapy using Mitomicin C and 5-Fluorouracil was retrospectively studied. An analysis of clinical features of these patients was performed using survival as an end point for evaluation of prognosis.
Results: These data suggest that the clinical features to be used to select patients for cytoreduction were completeness of resection at the time of the cytoreductive surgery, as 64 per cent of patients were alive at 3 years if no visible tumour remained or implants were less than 0·25 cm in diameter, but none was alive when tumour implants persisted greater than 0·25 cm in diameter (P=0·04). A peritoneal cancer index (PCI) was calculated by combining the lesion size and the abdominopelvic regions

affected, providing a score for composite involvement of the disease that was in close relation with survival. Patients with 12 or less PCI showed a statistically significantly better prognosis than those who had a higher score (P=0·066).

Conclusions: A peritoneal curative intent should be considered in patients with limited distribution and volume of peritoneal carcinomatosis defined by the Peritoneal Cancer Index (PCI).

Comparison of large bowel anastomoses using biofragmentable anastomotic ring and single layer continuous suture: a prospective randomized study

D. Görög, A. Péter, J. Szabó, A. Tóth and F. Perner
Transplantation and Surgical Clinic of Semmelweis Medical University, Budapest, Hungary

Background: Nowadays the biofragmentable anastomotic ring is widely accepted in colonic surgery, but there is less experience with using one layer continuous suture.

Aim: This prospective, randomized study was to compare the efficacy of the sutured anastomosis with the biofragmentable anastomotic ring (BAR) in colonic surgery.

Patients and methods: All patients undergoing elective colon resection between 1 April 1995 and 31 December 1997 were included in the study. Only if the ratio of bowel lumens at the site of anastomosis was larger than 1·7:1 the patient was excluded and in this case end to side anastomosis was performed. In the study group all anastomoses were constructed end to end.

Results: From 69 patients with end to end colonic anastomoses 32 were randomized in the suture group (12 ileocolic and 20 colocolic anastomoses). The BAR group included 14 patients with ileocolic and 23 patients with colocolic anastomoses (n=37). The mean age of patients with BAR anastomosis was higher (66 years) than those with sutured anastomosis (62 years). There was no significant difference between the two groups considering body mass index, ASA score, the ratio of benign and malignant diseases and TNM staging. In the suture group one patient (3 per cent) with multiple liver metastases died in the early postoperative period. There was no operative mortality in the BAR group. Two patients (5 per cent) with anastomotic leakage after BAR anastomosis were treated with Hartmann's procedure. There were not clinical signs of leakage in the suture group. From the five (14 per cent) surgical complications in the BAR group three required re-operation. Only a few postoperative complications, two wound sepsis, a deep venous thrombosis and a cardiac arrhythmia were observed in the suture group (12·5 per cent). Duration of BAR anastomoses was shorter than duration of sutured one (15 vs 18 minutes), but the overall duration of operation and hospital stay were nearly the same in the two groups.

Conclusions: These results suggest that the single layer continuous suture is as safe as the BAR for colonic anastomoses. The higher percentage of re-operation in the BAR group was due to the inadequate purse-string sutures in the first five cases and the higher age of patients. The BAR anastomoses cost 15 times more than their sutured counterparts.

Loop ileostomy is a method for temporary faecal diversion

L. Hornok, B. Lestár, E.M. Gamal, S.Z. László, L. Ritter and J. Kiss *Department of Surgery, Faculty of Postgraduation, HI University for Health Sciences, 1389 Budapest, Szabolcs u. 35, P.O. Box 112, Hungary*

Aims: Loop ileostomy is a feasible method for temporary diversion of faecal stream in colorectal surgery. The technical steps of the operation and the aetiology of complications are discussed along with the characteristic features of the postoperative period.

Materials and methods: During the period from November 1992 to March 1996, 34 loop ileostomies were created and restored usually after 14 weeks. The loop ileostomy protected the suture lines of 15 ileoanal anastomoses, of 18 colorectal or coloanal anastomoses and of one perineal construction. Loop ileostomy was supported by a rod inserted beneath the intestine, the afferent limb was averted and the mucocutaneous line was created. Complete diversion of the faecal stream was achieved in all cases. High-volume faecal output necessitated the administration of Imodium in 26 per cent of the cases. However, permanent parenteral fluid and electrolyte replacement was unnecessary. Stoma necrosis, bleeding, prolapse or retraction did not occur. Stomas were closed intraperitoneally in all cases but one. Two asymptomatic hernias were observed at closure. The continuity of the intestine was restored by the inversion of the previously opened and averted intestine in 13 cases, or by small resection in 21 cases (14 end-to-end, seven side-to-side anastomoses).

Results: The average length of the postoperative hospital stay after closure was nine days. Passage of the intestinal contents started 3 days following the closure in patients with ileoanal anastomosis and 2 days in patients with colorectal anastomosis. Clinical signs of prolonged postoperative ileus were observed in five cases, re-operation was necessary in two cases due to mechanical bowel obstruction. Wound infection developed in three cases.

Conclusion: Loop ileostomy is a simple and effective method for the temporary diversion of faecal stream with low morbidity. The creation and closure of loop ileostomies was not associated with any mortality.

Functional results of sphincter-saving surgery for distal rectal cancer

G. István, S. Kiss, I. Sugár, P. Ondrejka, Gy. Ledniczky and J. Faller *Semmelweis University, School of Medicine and Szt. János Hospital Department of Surgery, Kútvölgyi u. 4, H-1125 Budapest, Hungary*

Sphincter saving resection with low colorectal or coloanal anastomosis, as the alternative to abdomino-perineal excision should provide not only safe oncological outcome, but also good functional results.

The aim of this study was to assess the functional results of low rectal resections. The records of 27 patients who underwent rectal resection with low colorectal or coloanal anastomosis (and who had their diverting colostomies closed) from 1 January 1994 to 31 December 1996 were reviewed. There were 17 men and 10 women, with the mean age of 61·8 (38–78) years. The mean distance of the tumour from the anal verge was 6·9 (4–10) cm. The surgical technique was anterior resection (AR) in 16 cases and abdomino-transsphincteric resection (ATSR) in 11 cases. The anastomosis was made by hand sutures in four cases, by EEA stapler in six cases and with double stapling technique in 17 cases. A diverting colostomy was performed in 22 cases. Anastomotic leakage occurred in five cases (18·1 per cent).

The mean time elapsed from the closure of diverting colostomy was 19·7 (3–46) months. The continence was assessed by personal interview and classified according to Kirwan–Fazio. We found: 13 patients with normal continence, eight patients with the continence of gases impaired, four patients with occasional, minor soiling and two patients with frequent soiling. The mean stool frequency was 2·7 (1–12) per day. The stool frequency has decreased and the continence score has improved in time. No major soiling was found after six months from the stoma closure. No significant difference related to the type of resection (AR or ATSR) or to the suture technique was found. All the patients are satisfied with their sphincter function and prefer it to the colostomy.

These data confirm that sphincter-saving procedures for distal rectal cancer provide good functional results.

The phantom rectum: fact or fiction?

I.V. Mohan, R.T.A. Chalmers, J. Hamilton and A.R. Turner
Queen Margaret Hospital, Whitefield Road, Dunfermline, Fife, Scotland, UK

Aim: To investigate the prevalence of phantom perineal sensation following rectal amputation.

Methods: An audit database and stoma care records identified 60 patients who had regular stoma therapy following abdomino-perineal resection and pan-proctocolectomy. A postal questionnaire was sent to all patients and replies were cross-referenced with hospital records for accuracy.

Results: Forty-three patients responded (72 per cent). Median age was 67 (range 20 to 87) years. Median follow-up was 48 (range 3–369) months. Thirty-one patients (72 per cent) experienced phantom perineal sensation. This was described as the need to pass faeces rectally in 21 patients (68 per cent), need to pass wind in 15 (48 per cent), a dull ache in 12 (39 per cent) and nine patients (29 per cent) experienced shooting pains. The duration of symptoms was usually one to two minutes but ranged from a few seconds up to two hours. In 30 of the 31 symptomatic patients (97 per cent), the symptom remained the same or became less severe with time, and completely disappeared in 25 per cent (eight patients) within 6 months. Nine patients (29 per cent) described the symptoms as distressing. Four patients (13 per cent) experienced symptoms related to stoma function. Four patients experienced relief by pressure on the buttocks, two with analgesia and one patient by sitting on a toilet seat. Six patients (19 per cent) sought medical advice because of this symptom: relief was obtained by reassurance in three cases, simple analgesics in two cases; and one was found to have tumour recurrence. No patient had a further surgical procedure. The majority of patients expressed a desire to have been warned to expect these symptoms.

Conclusions: Phantom perineal sensation is a real phenomenon, but does not appear to be a long-term clinical problem. Pre-operative patient counselling may relieve distress, although in all cases tumour recurrence should be excluded.

Has the surgical technique of choice in complicated acute diverticulitis changed? A prospective non-randomized study of 185 patients

F. Sanchez-Bueno, L. Martinez de Haro and P. Parrilla Paricio
General Surgery Department, Virgen de la Arrixaca University Hospital, Murcia, Spain

Aim: To analyse 265 patients diagnosed with acute diverticulitis over a period of 20 years, comparing the indications and surgical techniques performed in two consecutive 10-year periods, together with the morbidity and mortality rates of the series.

Material and methods: A prospective study was made of 185 cases (group B) over a period of 10 years (1987–1996), who were compared with a retrospective series of 80 patients (group A) (1977–1986). 53·5 per cent of the patients required surgery whereas the remaining 46·5 per cent were treated conservatively. The indications for surgery were faecal peritonitis (16 cases), purulent peritonitis (39 cases), pelvic abscesses (40 cases), pericolic abscesses (nine cases), intestinal obstruction (15 cases), recurrent diverticulitis (19 cases) and colovesical fistula (four cases). The most commonly employed surgical techniques were resection and closure of the stump according to Hartmann (82 cases), without significant differences between the two periods, and resection with primary anastomosis (40 cases), with significant differences between the periods (14·8 per cent vs 36·3 per cent in group B) ($P<0·05$). 42·7 per cent of the patients undergoing the Hartmann operation had reconstruction of digestive continuity in a second intervention.

Results: There were postoperative complications in 40·1 per cent of the patients without statistically significant differences between the two periods. The postoperative mortality rate was 9·1 per cent, with statistically significant differences (14·8 per cent vs 5·7 per cent in group B) ($P<0·05$).

Conclusions: In our experience, the Hartmann operation is an efficient surgical procedure, especially if there is purulent or faecal contamination of the abdominal cavity, but we advocate resection with primary anastomosis following intraoperative lavage of the colon in the early stages of peritoneal contamination due to the minimum morbidity and zero mortality rates.

Surface hydrophobicity human colonic mucosa: role of epidermal growth factor

*J.L. Sánchez, *B. Sainz, *R. Pérez, *E. Espín, *M. Cano López, *F. De Lara, *M. Armengol, †A. Lujea, †F. Guarner and †J.R. Malagelada **Department of Surgery, †Digestive System Research Unit, Hospital General Vall d'Hebron, Departamento de Cirugía, 5ª Planta, Paseo Valle Hebrón 119-129, 08035 Barcelona, Spain*

The colonic mucosal barrier is a complex physico-chemical structure that separates the internal 'mileu' from a polluted luminal environment. Animal studies have shown that the barrier includes a strong hydrophobic surface to prevent the flux of water-soluble toxins in the epithelium.

Our aim was to explore the hydrophobic properties of the human colonic mucosa. Colonic specimens were obtained at surgery from patients undergoing colectomy for neoplasm (n=38) or diverticulitis (n=5). Preparation for surgery was similar in all patients and included antibiotic therapy (erithromycin-neomycin) and gut lavage with PEG solution. Specimens from normally appearing colon were washed in saline, and the mucosa was dissected and sectioned in 3 × 2 cm samples. In total, surface hydrophobicity was measured in 83 separate colonic samples by the contact angle that conform a 5 µL drop of saline deposited on the mucosal surface using a special goniometer. Large contact angles are read on hydrophobic surfaces whereas small angles are formed on hydrophillic surfaces. In four patients, nine samples were assessed straightforward after surgery, and 14 samples were incubated for 60 minutes with or without epidermal growth factor (EGF, 2 µg/mL) Krebs–Ringer (pH 7·4) at 37°C prior to hydrophobicity measurement. Phospholipid content was measured in homogenates of 25 samples.

Results: Mucosal hydrophobicity was similar in right colon (40±1·0°), left colon (42±0·9°) or rectum (42±0·8°). Likewise, no difference was found in phospholipid content between right colon (202±1·2 mol/g), left colon (199±17) or rectum (226±23). Incubation of mucosal samples increased surface hydrophobicity (baseline: 39±0·4°; post-incubation: 44±1·8°, P 0·05), suggesting active release of surfactant. Exposure to EGF significantly increased hydrophobicity (49±1·6°) as compared to incubation without EGF (44±1·8, P 0·05).

Conclusion: The human colonic mucosa exhibits a hydrophobic surface, which can be regulated by endogenous growth factors such as EGF.

Cost-benefit problems in colorectal surgery in Hungary

I. Zöllei *Surgical Department of Albert Szent-Györgyi Medical University, Szeged, Hungary H-6720 SZEGED, Pécsi Street 4, Hungary*

The costs of surgical procedures are increasing all over the world, because of new technical instruments and high salaries of surgeons and their assistants. That is a great problem in Hungarian hospitals, because the relatively low Hungarian GDP allows less and less budget for the hospital costs. The prices of instruments are well determined, but the prices of 1 hour's work in the operating room is not fixed even today in Hungary.

Clinical study was performed between 1st January 1990 and 31st December 1997. The goal of this study was to compare the perioperative data of patients with elective colorectal resections because of malignancies. The operator and the preoperative preparation of patients were the same. The patients were divided into two groups. One group had operations with colon-anastomosis, the other with rectal anastomosis.

Data of 203 patients (105 female and 98 male) were analysed. One hundred and sixteen anastomoses were performed on the colon (68 of them were hand sewn and 48 were made by linear staplers). The rectal operations were divided into three groups. There was a group for patients with hand sewn anastomoses, a group for patients with anastomoses sutured by one EEA circular stapler, and there was one group for patients operated on with double-stapler technique. The groups were comparable. Distribution of sex, mean age and mean body weights were similar.

The mortality and complication rates were similar in the groups of patients with colon anastomoses. But the operative time was significantly shorter in the group of anastomoses made by linear staplers. Unfortunately, the cost of operation was higher because of prices of linear staplers. The author could not determine how much cost was spared by the shorter operating time.

The mortality rates were similar in the groups of patients with rectal anatomoses. The complication rate was the lowest and the operating time was the shortest in the double stapling group. Unfortunately, the cost of operation was the highest in that group because of the prices of two staplers. The authors could not determine how much cost was spared by the shorter time and the lowest complication rate.

The role of immunological factors in wound infections (a prospective clinical study)

N. Akyürek, A. Bedirli, O. Yüksel, M. Kerek and M. Keçeci *Erciyes University, Medical Faculty, General Surgery Kayseri, Turkey*

Wound infections are observed in 1·5–4 per cent of clean and 28–40 per cent of contaminated wounds. One of the intervening factors in the development of wound infections is the present immunological status of the patient.

Aim: To investigate the relationship between the immunological status of the patients and wound infections. The effect of different treatment modalities on the immunological status of the patients and the state of immunological parameters as being criteria in the efficiency of the treatment have also been investigated.

Materials and methods: Wounds were grouped into three as clean, clean-contaminated and dirty wounds. Each group consisted of 15 patients. The patients who had received radiotherapy or chemotherapy and who were immune compromised were excluded from the study. T-lymphocyte (CD3+), B-lymphocyte (CD19+) and total lymphocyte (CD45+) counts, and IgG, IgM and IgA levels were measured at the beginning of treatment, at the fifth and tenth days. The immunological changes were compared within and between the groups with ANOVA test.

Results: The levels of CD3+, CD19+, CD45+, IgM, IgA were not different in all the groups, while in the dirty group, IgG levels were lower than the other groups at the beginning of the treatment ($P<0\cdot05$). At the fifth and tenth days of the treatment, IgG levels increased and CD19+ level decreased in the dirty group ($P>0\cdot05$). Two patients in the contaminated group died during the treatment. These two patients had a progressive decrease in the levels of IgG and CD19+ ($P>0\cdot05$). There was no change in the levels of CD3+, CD19+, CD45+, IgG, IgM and IgA in the clean and clean-contaminated groups at the fifth and tenth days of the treatment.

Conclusions: The possibility of development of wound infection is higher in the patients having lower IgG at the beginning of treatment and in the patients having progressive decrease of CD19+ levels during the treatment.

The value of augmentin prophylaxis in colorectal surgery: a double blind randomized prospective study

Á. Balogh, G. Lázár, I. Zöllei and E. Szederkényi *A. Szent-Györgyi Medical University Department of Surgery, Szeged, Hungary, PO Box 464, H-6701*

Authors report a double-blind randomized prospective study to evaluate the efficacy of Augmentin in the pretreatment of elective colorectal operations. In this comparative (Augmentin vs Zinacef-Metronidazole) randomized, one day prophylaxis trial 90 patients were involved. In group A the randomly selected 40 patients were pretreated with Augmentin (3·6 g/day) and 50 patients in group B with Zinacef-Metronidazole combination (4·5 g/day Zinacef and 1·5 g/day Klion). The factors potentially influencing the results – age, stage of the disease, type of surgery, risk factors, accompanying diseases – were similar in the two groups. The efficacy of antibiotic prophylaxis has been compared based on time of postoperative hospitalization, wound healing, rate of septic complications, etc. The average number of postoperative hospitalization days showed no significant difference: 14·9 days in group A, and 12·3 days in group B. The mortality rate of the 90 patients was 2·2 per cent. Both patients died from group A, so the rate of mortality in group A has been 5 per cent, and 0 per cent in group B. The rate of septic complications was 27·5 per cent in group A while the one in group B has been only 20 per cent. Our results show that the efficacy of Zinacef-Metronidazole combination seems to be superior related to the solitary Augmentin pretreatment in colorectal surgery.

Bileodigestive anastomosis or external drainage of the biliary tree in benign diseases of the gallbladder

K. Dimitrova, I. Ratchev and R. Gudzenko *Russe, No 56, Pleven 5800, Bulgaria*

Patients with diseases of the gallbladder tend to increase annually judging from our data and from reports in literature.

In the first surgical department of the Medical University Pleven during the period 1990–1997, 1134 patients were operated for benign diseases of the biliary tree, gallbladder and pancreas either on emergency basis or planned. We report 324 patients in whom we performed cholecystectomy with temporary or permanent drainage of the bile.

The aim of the study was:

1. Definition of indications for performing one or another operation.
2. Comparison of results from treatment modalities – during the course of the study the criteria for choledochotomy was defined – stones in the ducts choledochus, expanded ducts choledochus, purulent cholangitis, biliary fistulas, mechanical jaundice.

Choledocho-duodenal anastomosis and choledochotomy with external drainage have their respective indications. We recommend choledocho-duodenal anastomosis.

Vancomycin prophylaxis for MRSA wound infections

P. Lintott, R. Chalmers, A.O. Mansfield, A. Nicolaides, N. Cheshire, J. Wolfe and G. Stansby *Academic Surgical Unit, ICSM at St. Mary's, London, UK*

Introduction: The incidence of methicillin-resistant *Staphlococcus aureus* (MRSA) infections is increasing. This is of particular importance in vascular surgery where graft infection is associated with a significant mortality. We have therefore reviewed the incidence of MRSA wound infections following the contribution of three doses of 500 mg vancomycin i.v. as part of the routine prophylaxis for major vascular procedures on our unit.

Method: Patients were included from January 1996 to May 1997. Inter-hospital transfers and patients previously known to harbour MRSA were screened on admission to the unit. Only patients without known MRSA infection or colonization and having major vascular procedures from our vascular ward or the ITU are included. Postoperatively wound swabs were taken if there was clinical suspicion of infection or if MRSA was isolated from another site.

Results: Before the introduction of the vancomycin there were six MRSA wound infections in 122 patients (4·92 per cent), after there were 16 infections in 344 patients (4·65 per cent). The number of MRSA-positive patients admitted to the ward per month was constant throughout the period studied (median 1, range 0–3). Furthermore, the number of operations and discharges per month were also constant (median 47, range 30–55 and median 44, range 31–62 respectively). The total number of MRSA wound infections from all procedures performed was 1·6 per month before May 1996 and 1·58 thereafter (i.e. 4·02 per cent and 3·58 per cent respectively).

Conclusion: The policy of vancomycin prophylaxis has had no significant effect on MRSA wound infection in the period studied.

Peritoneal and biliary penetration of selected antibiotics in surgical inflammatory conditions

J. Mészáros, A. Chmura, M. Kosieradzki, W. Lisik, J.J. Mészáros and W. Rowiński *Department of General and Transplantation Surgery, Medical University of Warsaw, 59 Nowogrodzka St, Warsaw, Poland*

The study was undertaken to estimate the peritoneal and biliary penetration of ceftazidime, cefoperazone, amikacin and netilmicin – drugs useful in the treatment of intra-abdominal sepsis. The trial included patients given an antibiotic in the perioperative period either as a prophylaxis or a treatment of infection.

Samples of serum, peritoneum and bile were obtained on operation after the patient was administered the first dose of an antibiotic preoperatively. Concentrations of drugs were determined by bioassay in an agar well diffusion method. Concentration of an antibiotic was assessed with standard strains: *E. coli* ATCC 25922 for cefalosporins and *B. subtilis* ATCC 6933 for aminoglycosides. Time-course drugs concentrations was calculated with the least-squares regression analysis.

One hour after 2 g of cefoperazone administration in 28 patients its peritoneal concentration was within therapeutic range (~30 μg/g) and was maintained on more or less same level for next 4–5 hours, with little patient-to-patient deviation.

Maximum ceftazidime concentrations (17 patients), exceeding 40 μg/g, were observed also one hour post injection, but major differences between patients were noted.

Amikacin (13 patients) reached maximum level in the peritoneum (~4 μg/g) 3 hours after administration followed by its slow decrease, parallel to that in the serum. Netilmycin concentration (in 30 patients) exceeded and was maintained longer than that of amikacin, reached maximum values one hour post administration and was kept stable for next three hours. Seven hours following administration it was still well above 3 μg/g.

Biliary concentration of cefoperazone was assessed in two groups of patients: with and without jaundice. Maximum concentration of the drug in patients without evidence of jaundice (20 patients) after administration of 1 g exceeded 500 μg/ml and was maintained for 3 hours and followed by a slow decrease – seven hours after administration it was about 10 per cent lower than maximum value.

Ceftazidime (seven patients) reached maximum level (45 μg/ml) in 1 hour and was followed by a slow elimination phase parallel to the serum drug kinetics.

Both aminoglycosides reach maximum biliary levels (~4 μg/ml) after 3 hours, but netilmycine (20 patients) maintains its concentration for next 4 hours, while amikacine (15 patients) level falls proportionally to its blood concentration and after 7 hours is only 1 g/ml.

Clostridium difficile infections in our practice of colorectal surgery

I. Sugár, J. Faller, L. Drexler, P. Ondrejka, Z. Ráth and G. István *Semmelweis University School of Medicine, St. John Hospital, Department of Surgery, Kútvölgyi u. 4, H-1125 Budapest, Hungary*

Clostridium difficile (CD) is an anaerobic bacterium which may cause severe entero-colitis. Its relatively high incidence in colorectal surgery may be due to the use of antibiotics in the bowel preparation and in the postoperative period. The three clinical forms of CD infection, in order of increasing severity, are: 1) antibiotic associated diarrhoea (AAD); 2) antibiotic associated colitis (AAC); and 3) antibiotic associated pseudomembranous colitis (AAPMC).

The records of 1215 patients who underwent colorectal operations from 1988 to 1997 in our department have been reviewed. The diagnosis of CD infection was based on bacterial culture and on a specific cytotoxin assay of the stool.

The different protocols of preoperative antibiotic prophylaxis (Cefuroxmin + Clindamycin, Cefotaxim + Metronidasol, Sulbactam + Ampicillin, Amoxicillin + Calvulanic ac. + Metronidazol) did not show significant difference in the rate of CD infections.

After having reported elsewhere four severe cases of AAPCM in the first five year period (1988–1992), in the second period (1993–1997) we have made changes in the bowel preparation protocols, the suspicion of CD infection was questioned earlier and the specific laboratory tests were used more often in CD infection suspect cases.

Period	No. of patients	Negative test	AAD	AAC	AAPCM
1988–1992	604	33 (5·5%)	59 (9·8%)	13 (2·1%)	4 (0·7%)
1993–1997	611	57 (9·3%)	30 (4·9%)	13 (2·1%)	2 (0·3%)

Metronidazole was the therapy of first choice in test positive cases. If the clinical signs did not show improvement after 24 hours, Vancomycin therapy was started.

Zinc as an inhibitor of apoptotic DNA fragmentation in isolated perfused rat liver

*A. Amin, †S. Mohammed, *B. Fuller, †K.S. Sari, *M. Winslet and *C.J. Green **University Department of Surgery, †Department of Biochemistry and Molecular Biology, Royal Free Hospital School of Medicine, London, UK*

Zinc is an important intracellular ion with many important biological effects, including preventing DNA fragmentation due to apoptotic cell death. We have successfully achieved blockage of DNA fragmentation in apoptosis induced by bloodless perfusion in IPRL.

Our model of apoptosis involves perfusion of rat liver with modified Krebs solution containing glucose and hydroxyethyl starch at 37°C, either after flushing with cold UW and 24 hour storage at 4°C in the same solution, or flushing only without preservation. Perfusion flow rate was 2·5–3 ml/gm/min. Liver specimens were collected at 0, 1, 3, 5 hours and freeze clamped in liquid N_2. DNA was isolated using standard phenol chloroform extraction and electrophoresed on 1·5 per cent w/v agarose gel, stained with ethidium bromide 40 µg/L (w/v) and visualized by UV light.

A single band of genomic DNA close to the loading point was found in all livers perfused with zinc 25 µM + zinc ionophore 4 µM rich solution (n=8) between 0–5 hours perfusion. In contrast, perfusion of livers by calcium-channel blocking agents verapamil (50 mg/kg) or chlorpromazine (25 mg/kg) containing solution were without suppression of apoptosis. The DNA ladder was comprised of frequent multiples of approximately 200 base pairs. In addition, livers cold preserved in zinc and ionophore containing UW solution and perfused with Krebs solution only had shown no suppression of DNA degradation.

In summary, DNA laddering pattern characteristics of apoptosis disappeared consistently in rat livers perfused with zinc sulfate treated solution. Addition of calcium antagonist was without effect. Further study to investigate the mechanism of DNA fragmentation blockage by zinc is required.

Isolated perfused rat liver: a model of induction of apoptosis by bloodless perfusion

*A. Amin, †S. Mohammed, *B. Fuller, †K. Srai and *M. Winslet **University Deparment of Surgery, †Department of Biochemistry and Molecular Biology, Royal Free Hospital School of Medicine, London, UK*

Apoptosis or programmed cell death is an active mechanism, with well-described morphological and biochemical components and is a known physiological process initiated by a variety of stimuli including renal ischaemia. We here investigated apoptosis as indicated by characteristic DNA degradation or laddering in isolated perfused rat livers (IPRL).

Rat livers were flushed with cold solution and perfused with modified Krebs' solution containing glucose and hydroxyethyl starch (COLLOID) at 37°C and oxygenated with 95 per cent O_2 and 5 per cent CO_2. Perfusion flow rate was 2·5–3 ml/gm/min. Liver specimens collected at 0, 1, 2, 3 hours and freeze clamped in liquid N_2. DNA was isolated using standard phenol chloroform extraction and electrophoresed on 1·5 per cent w/v agarose gel, gel stained with ethidium bromide 40 µg/L (w/v) and visualized by UV light.

A single band of genomic DNA close to the loading point was found in all livers (n=4) between 0–2 hours perfusion. In contrast, we found DNA laddering indicative of apoptosis at 3 hours perfusion in all livers. The ladder was comprised of frequent multiples of approximately DNA 200 base pairs. Livers (n=4) flushed with warm solution (37°C) to avoid temperature shock also showed laddering at 3 hours. Changing the perfusion system from non-recirculating modes to recirculating did not prevent DNA laddering after 3 hours perfusion. Addition of thiol-saving agents reduced glutathione (500 mg/L) and N-acetyl cysteine (300 mg/L) were also without effect. Recent histological examination has confirmed the appearance of apoptotic bodies in the tissues of IPRL.

In summary, IPRL under these conditions consistently produces DNA laddering after 3 hours and may be a model to investigate pharmacological interventions in apoptosis.

Significance of biochemical parameters in early diagnosis of strangulated bowel obstruction (experimental study)

M.L. Akin, I. Ezedin, C. Erenoglu, E. Filiz, S. Aydin and A. Batkin *Gata Haydarpasa Egitim Hastanesi, Genel Cerrahi Servisi, Kadikoy, 81327 Istanbul, Turkey*

Aim: Although the diagnosis of simple mechanical bowel obstruction is easy and prognosis is good, the surgical timing is quite difficult in strangulated cases where a delay in diagnosis may effect the morbidity and mortality adversely. The value of biochemical parameters in early diagnosis of strangulated bowel obstructions in rats with simple and strangulated bowel obstruction was investigated in this study.

Materials and methods: Fifty male Wistar Albino rats were used. Rats were separated into two groups of 20 rats and one group of 10 rats. In the first group (control group-CG) laparotomy only was applied and 1 ml of blood sample was withdrawn. In the second (simple obstruction group-OG) and third (strangulated obstruction group-SOG) groups simple or strangulated obstruction 5 cm proximal to ceacum was established. Two and 12 hours postoperatively in the first 10 rats, and 4 and 24 hours postoperatively in the other 10 rats 0·5 ml of blood samples were withdrawn. Analyses of lactic acid (LA), lactic dehydrogenase (LDH), creatine phosphokinase (CPK) and amylase were done.

Results: Serum LA, LDH, CPK and amylase values were significantly higher (P<0·05) in OG and SOG at 2 hours postoperatively and during 24 hours than those of CG. But only LA and amylase values were significantly higher (P<0·05) in SOG at 2 hours postoperatively and during 24 hours than those of OG.

Conclusions: It is concluded that although the serum LA and amylase values are not specific for bowel obstructions, it may be valuable in early diagnosis of strangulated bowel obstructions if their levels are found to be elevated in the early stage of strangulation.

The effects of dimethylsulfoxide in liver ischemia

E.M. Kafalı, N. Akyürek, A. Bedirli and S. Muhtaroğlu *Erciyes University, Medical Faculty, General Surgery 38039 Kayseri, Turkey*

Aim: We determined the biochemical and cellular changes arising in liver during the ischaemia period of Pringle manoeuvre and then did research into the effects of DMSO, non-enzymatic oxygen free radical scavenger and Na^+-K^+-ATPase inhibitor.

Material and methods: Twenty-four albino rabbits of New Zealand type weighing 2350–2550 g were used. The experiment consisted of two groups, called study and control. In the study group, Pringle manoeuvre was applied for 60 minutes, but no application was made in the control group. The study and control groups were divided into two groups of six rabbits as those given and not given DMSO.

Results: In the ischemia group given DMSO the decrease in the blood glucose values turned into increase after the 30th minute. There was a decrease of 29 per cent in glycogen values after 60 minutes ischaemia in the ischaemia group not given DMSO, this decrease was 20 per cent in the ischaemia group given DMSO. The increase in LDH and AST levels was not statistically meaningful in the ischaemia group given DMSO (P>0·05). It was shown that DMSO did not have a preventive effect on the increase in ALT values occurring in the liver ischaemia (P<0·05). The decrease in ATP level was found only meaningful in the group given DMSO (P<0·05). It was observed that DMSO caused MDA levels increasing after the liver ischaemia to decrease meaningfully (P<0·05). In the ischaemia group after DMSO was given, the increases in SOD levels in the erythrocyte were not meaningful (P>0·05) and GSH-rd levels went down quite meaningfully (P<0·01). DMSO causes a decrease after 30th minute in GSH-px values going up in the liver ischaemia (P<0·01).

Conclusion: It was observed that DMSO had a positive effect in the experimental liver ischaemia on the values of blood glycose, liver glycogen, blood ATP, AST, LDH, blood and tissue MDA, GSH-px, GSH-rd and SOD in accord with the purpose of the experiment. However, no positive effect on ALP and ALT values was observed. DMSO may be used in order to reduce the negative effect of ischaemia in the liver tissue.

The effect of aminoguanidine and L-Arginine on neutrophil chemotaxis and bacterial translocation in rats after endotoxin challenge

M. Bayrak, T. Coskun, N.A. Kama, *B. Sener, †I. Cinel and ‡L. Cinel *Ankara Numune Hospital, 4th Department of Surgery, Turkey, *Hacettepe University Medical School Department of Clinical Microbiology, †Ankara Numune Hospital, Department of Anesthesiology, ‡Zekai Tahir Burak Woman Hospital Department of Pathology*

Aim: Inhibition of neutrophil chemotaxis and increased bacterial translocation are the two important factors associated with high mortality in sepsis. In this study, we aimed to investigate the effect of inhibition of nitric oxide synthase (NOS) with aminoguanidine (AG), which is relatively more specific for inducible NOS, and administration of a nitric oxide precursor, L-Arginine, on neutrophil chemotaxis and bacterial translocation in a rat sepsis model.
Material and methods: Sixty male Wistar Albino rats were randomly assigned into six groups: (1) group 1, normal saline solution (NSS, 0·6 ml/kg/h for 4 hours); (2) group 2, lipopolysaccharide (LPS, 10 mg/kg intraperitoneally 2 hours before the experiment); (3) group 3, NSS and aminoguanidine (AG, 5 mg/kg bolus and 5 mg/kg/h infusion for 4 hours); (4) group 4, LPS and AG; (5) group 5, NSS and L-Arginine (L-Arg, 100 mg/kg/h infusion for 4 hours); (6) group 6, LPS and L-Arg. Additionally, rats in all groups received 15 ml of sodium caseinate intraperitoneally, 12 hours before the experiment for the study of chemotaxis. Animals underwent laparotomy at 4 hours of experiment. Peritoneal fluid was taken for the study of neutrophil chemotactic index (ratio of chemoattractant-induced neutrophil migration in micrometers to random migration); tissue samples of liver, spleen, mesenteric lymph nodes, ileum and caecum were taken for histological examination and bacterial translocation studies. For statistical analyses, Duncan multiple range test, Friedman test and χ^2-square tests were used.
Results: LPS given intraperitoneally was found to inhibit neutrophil chemotaxis and increase bacterial translocation statistically in this model. L-Arg and AG administration significantly increased chemotactic index and decreased translocation after endotoxin challenge (Table 1). Despite the decrease in bacterial translocation and bacterial population level in cecum after AG administration in septic rats, these figures were significantly high when compared with normal rats. On the other hand, L-Arg decreased translocation and bacterial population in cecum to the levels found in normal rats and preserved mucosal integrity in small intestine in septic rats.

Groups	Chemotactic index (mean±s.d.)	Translocation incidence to mesenteric lymph nodes	Bacterial population in cecum ($\times10^6$/gram-tissue)	Intestinal mucosal damage score
NSS	1·60 (±0·23)	0/10†	0·4±1·8Ê	9§
LPS	1·26 (±0·10)	9/10	5·5±4·2	21
NSS+AG	1·04 (±0·04)	–	–	–
LPS+AG	1·80 (±0·16)*	4/10†	2·3±2·4†	16
NSS+L-Arg	1·68 (±0·03)	–	–	–
LPS+L-Arg	1·79 (±0·01)*	0/10†	0·5±1·1†	11§

NSS, normal saline solution; LPS, lipopolysaccharide; AG, aminoguanidine; L-Arg, L-Arginine; *$P<0{\cdot}05$ LPS+L-Arg and LPS+AG vs NSS and LPS; †$P<0{\cdot}05$ LPS+AG vs LPS; ‡$P<0{\cdot}05$ NSS vs LPS+AG; §$P<0{\cdot}05$ NSS and LPS+L-Arg vs LPS.

Conclusion: The results of this study have shown that administration of L-Arginine and aminoguanidine induced neutrophil chemotaxis and increased chemotactic index after endotoxin challenge in rats. Additionally, L-Arginine preserved intestinal mucosal integrity which, in turn, inhibited bacterial translocation in this sepsis model.

The role of oxygen free radicals and nitric oxide in haemorrhagic shock and tissue injury due to reinfusion

A. Bedirli, E.M. Sözüer, E.M. Kafalı, M. Alper and S. Muhtaroğlu *Erciyes University, Medical Faculty, General Surgery Kayseri, Turkey*

Aim: Haemorrhagic shock is a hypovolaemic condition that leads to haemodynamic decompensation associated with ischaemic metabolic insufficiency caused by inadequate tissue perfusion, altered cell membrane permeability and subsequent cellular dysfunction. Haemorrhagic shock followed by resuscitation is a generalized whole-body ischaemia-reperfusion insult. The purpose of the present study was to evaluate the role of oxygen free radicals and nitric oxide (NO) in physiological alterations and multiple organ damage caused by haemorrhagic shock and reinfusion.
Materials and methods: Twenty-six mongrel type dogs were used in this study. The dogs were let to bleed till the arterial blood pressure fell to 35 mmHg and they were kept in shock for 1 hour. Three randomized groups were formed. The control group ($n=10$) received 10 ml 0·9 per cent sodium chloride, the NO group ($n=8$) received 250 mg/kg L-arginine and L-NAME group ($n=8$) received 25 mg/kg L-NAME intravenously in the 55th minute of the haemorrhagic shock. After the shock period, the shed blood was returned. Blood and tissue samples were taken before experiment, after 1 hour of shock and 2 hours after the reinfusion. The biochemical results, enzyme, nitrite-nitrate levels were compared with ANOVA test and χ^2-square test was used for the evaluation of histopathological results.
Results: The mean arterial pressure fell after the infusion of L-arginin, whereas L-NAME infusion resulted in significant increase of blood pressure. The infusion of L-arginin after haemorrhagic shock was found to increase myocardical injury and renal dysfunction developing secondary to shock ($P<0{\cdot}05$). L-arginin was found to decrease hepotocyte and intestinal injury secondary to shock and reinfusion. L-arginin caused significant decrease of endogenous free radical scavengers within erythrocytes and liver tissue ($P<0{\cdot}05$).
Conclusions: NO infusion in haemorrhagic shock caused renal and myocardial injury by increasing hypoperfusion and had protective effect on liver and intestinal tissue, probably by adjusting the microcirculation. Whereas inhibition of NO synthesis aggravated reinfusion injury.

Prevention of peritoneal adhesions by streptokinase, phosphotidylcholine and diclofenac-sodium in New Zealand white rabbits

H.M. Cete, M.M. Özmen, Y. Erdem and S. Hengirmen *First Surgical Department, Numune Hospital, Ankara, Turkey*

The formation of peritoneal adhesions after operations remains a serious problem and is probably the most common cause of the intestinal obstruction. In this study we investigated the effect of three different agents in the prevention of peritoneal adhesions induced by caecal abrasions in New Zealand white rabbits. Group I ($n=16$) acted as controls. Group II ($n=16$) received 100 000 IU/kg streptokinase; group III ($n=16$) received 3 mg/kg diclofenac-sodium and group IV ($n=16$) received a total dose of 50 mg phosphotidylcholine given intraperitoneally in 20 ml saline just before the closure of abdominal cavity. Fourteen days later all animals were killed, abdominal cavity was inspected and assessed by two 'blind' surgeons who did not attend the initial operation using a new wide paramedian incision. All adhesions were graded from 0 to 4 according to Mazuji[1] and scored from 0 (grade 0, 1) to 1 (grade 2–3–4) according to Elkins[2]. Thirteen (81 per cent) animals in group I, 11 (69 per cent) in group II, 11 (69 per cent) in group III and six (37 per cent) in group IV had adhesions. The difference between control and phosphotidylcholine group was significant ($P<0{\cdot}03$), whereas no difference was observed among the other groups. The adhesions were significantly low graded in group IV than all other groups ($P<0{\cdot}005$). The scoring of the adhesions also revealed that the phosphotidylcholine group had only 2 (12·5 per cent) significant adhesions, which was 8 (50 per cent) in diclofenac-sodium group, 11 (69 per cent) in streptokinase group and 13 (81 per cent) in controls ($P<0·0006$ for group 4–1, $P<0·005$ for group 4–2, $P<0·05$ for group 4–3). This study suggests that the phosphotidylcholine is better agent than all others in reducing the incidence and severity of peritoneal adhesion formation induced by caecal abrasions.

The role of neurogenic inflammation in the process of healing of experimental colon anastomosis

F. Ender, E.M. Gamal and L. Rosivall *Department of Surgery, HIETE and Institute of Pathophysiology, SOTE, Budapest 1389 Budapest, Szabolcs u. 35, P.O. Box 112, Hungary*

Aim: The tissue perfusion enhancing neuropeptides which act in opposition to the sympathetic vasoconstrictor tone, seem to play an important role in the regulation of tissue microcirculation adjusted to the actual metabolism under different physiological and pathological circumstances The aim of this study was to explore the effects of inhibition of neurogenic inflammation, i.e. alteration in local neuropeptide activities on the healing process of experimental colon anastomosis
Materials and methods: Sigmoid colon anastomosis was performed in infant and adult male Wistar rats, which had been previously treated by Capsaicin In the second postoperative day the anastomosis bursting pressure (ABP) and the blood vessel permeability changes were registered by Evans Blue Extravasation Technique.
Results: In the adult Capsaicin-treated group the ABP value was 50±5 per cent more than the control group On the other hand, in the infant group the ABP was significantly higher than that of the control group (90±8 mmHg $n=11$ vs 54±5 mmHg $n=27$ $P<0·01$) In the adult treated group the Evans Blue extravasation was numerically lower than the control group
Conclusion: The inhibition or the damage to the Capsaicin sensitive C and A-delta nociceptive afferent fibres decreases the inflammation reaction in the area of the anastomosis and enhances its healing Our previous results suggest that the inhibition of the neurogenic inflammation may contribute to the increase of the number of the successful anastomoses

The influence of pneumoperitoneum on peritoneal implantation and growth of spleen cell suspension in an experimental model

E.M. Gamal, I. Furka, P. Metzger, I. Mikó, K. Tóth and J. Kiss
Department of Surgery, HIETE, Budapest and Department of Experimental Surgery, SOTE, Debrecen Department of Surgery, Faculty of Postgraduation, H.I. University for Health Sciences, 1389 Budapest, Szabolcs u. 35, P.O. Box 112, Hungary

Aims: An investigation of the effect of laparoscopy and CO_2 pneumoperitoneum on the pattern of tumour-like spleen tissue suspension implantation and growth in the intra- and extraperitoneal space was carried out
Materials and methods: Ten animal models weighing 15–20 kg were used, five for laparoscopy with pneumoperitoneum, three for gasless laparoscopy and two for laparotomy. Animals for gasless laparoscopy and laparotomy consisted the control group In all cases partial resection of the spleen of the animal model was carried out through a laparotomy and a 2 ml of homogenous spleen suspension was prepared in each case The spleen suspension was then placed in the subhepatic region In the laparoscopy group the laparotomy was closed and four 10 mm trocars were placed in the upper and lower abdomen and CO_2 was insufflated and desufflated in 10-minute intervals at each port site for one hour, followed by the removal of the trocars. In the control group of laparotomy the laparotomy was simply closed, and in the group of the gasless laparoscopy the abdomen was closed over a laparolift for also one hour, and then the lift removed and the incision was closed.
Results: All animals survived. Four weeks following the experiments all animals underwent re-laparoscopy to detect spleen tissue implantation and growth. In the group of the pneumoperitoneum excessive implantation was observed around the intra- and extraperitoneal port sites, and spleen tissue seeding was found in all the peritoneal surfaces of the abdominal cavity In the control groups only scattered spleen tissue implantation was detected intraperitoneally. Histological results confirmed these findings.
Conclusions: The results of this study support the issue of the role of pneumoperitoneum in the cellular aerolization, the implantation and the growth of spleen tissue intraperitoneally and in the extraperitoneal space when compared to laparotomy and gasless laparoscopy, supporting the postulate that early port side wound metastases and early carcinosis and tumour spread may be more likely following laparoscopic oncological surgery in humans when CO_2 insufflation and desufflation (Chimney effect) is used

Renal autotransplantation in extracorporeal renal surgery for severe renal vascular hypertension

G.M. Abouna, H.I. Al-Tareif, M.L. Al-Tareif, A.S. Al-Arrayed, A.H. Al-Awadhi and M. Tantawi *College of Medicine and Medical Sciences, Arabian Gulf University, P.O. Box 22979, Manama, Bahrain*

Introduction: Experience in renal transplantation has resulted in the development of extracorporeal surgical techniques to treat various vascular and urologic conditions of the kidney. Among the vascular problems which can be successfully managed by extracorporeal renal surgery and autotransplantation, are renal artery stenosis resulting from atheroma, fibro-muscular disease, segmental artery aneurysms.
Method: We have used the technique of extracorporeal hypothermic benchwork surgery with autotransplantation with renal vascular problems and severe hypertension requiring 3–4 drugs in three patients aged 16–30 years. Two patients had obstructing aneurysm of branches of renal artery and one had bilateral renal artery stenosis with severe myocardial dysfunction. All patients were evaluated according to a specific protocol, including renal function studies, isotope renograms, IVP, renal angiography and cardiac function studies. The kidney is removed after mobilization of the ureter and dividing both renal artery and vein. It is then immediately cooled by perfusion with Eurocollin solution and it is placed in a kidney dish outside the wound while appropriate bench surgery is carried out with magnifying loops. The kidney is then autotransplanted lower down in the abdomen on the common iliac artery and vein. The patient is placed on subcutaneous heparin for several days and then on oral aspirin.
Results: All patients fully recovered with normalization of their blood pressure and improvement in renal function with no anti-hypertensive medication. Renal isotope scan showed marked improvement in renal flow and function. In the patient with bilateral renal artery stenosis, post surgical cardiac study showed reversal of cardiomegaly with left ventricular diameter falling from 7 to 5 cm and the ejection fraction rising from 20 to 40 per cent within four months.
Conclusion: Extracorporeal renal surgery with autotransplantation is a very effective and successful method of renocascular hypertension of all causes and it should be more widely practised.

Are modular bifurcate aortic stent grafts (ASG) succeeding?

A.S. Brown *On behalf of Freeman Hospital, Newcastle upon Tyne and Royal Liverpool University Hospital. The Northern Vascular Centre, Level 4, Freeman Hospital, Newcastle upon Tyne, England*

Aims: To assess the mid-term results of the Vanguard ASG for the treatment of abdominal aortic aneurysms (AAA).
Methods: Over a 28 month period, 371 AAAs have been assessed using CT scans. Calibrating angiography was performed on 129, of which 64 were repaired using a Vanguard ASG. Patients have been followed up clinically and with regular contrast enhanced CT scans. Morbidity and mortality are assessed with particular reference to limb patency and perigraft flow (endoleak).
Results: All deployments were successful. Exclusion of the aneurysm sac was achieved in 55 patients (86 per cent). There were three deaths (perioperative mortality 4·7 per cent) but no major complications. Of four proximal endoleaks: one sealed spontaneously, one persists and two patients died following attempted open repair. Another patient died from an MI on day three. Of five endoleaks, three sealed spontaneously and two required further endovascular intervention. Six grafts have suffered unilateral limb occlusion and CT has identified three late distal endoleaks, each requiring endovascular repair. Three further patients have died (>30 days, two unrelated, one graft infection).
Conclusion: Mid-term results confirm that modular bifurcate ASGs are suitable for the treatment of selected AAAs. The development of late endoleaks is a cause for concern and continued follow-up is required.

Laparoscopic aorto-iliac reconstructive surgery: a prospective study

R. Kolvenbach, O. Deling, K. Wellmann and E. Schwierz *Department of Vascular Surgery, Augusta Hospital, Amalien Str. 9, 40472 Dusseldorf, FRG*

Most recently there have been several reports dealing with laparoscopically assisted aorto-iliac surgery. So far there has been no controlled study evaluating the possible benefits for the patient with aorto-iliac occlusive disease when this minimal invasive technique is used. It was the purpose of our study to assess the possible benefits of the minimal invasive technique and the consequences on the clinical course.
Material and methods: In a prospective controlled study lasting 11 months 24 patients with aorto-iliac occlusive disease were included into the study protocol. Exclusion criteria were aneurysmal disease, morbid obesity with a body mass index >30 or the necesssity for suprarenal aortic clamping. The control group consisted of 12 patients in whom a transperitoneal median laparotomy was performed for aorto-bifemoral bypass grafting. In the study group there were 12 patients who were operated using a transperitoneal minilaparotomy (5 cm) and a laparoscopically assisted approach. The aorta was dissected up to the origin of the renal arteries using the minilaparotomy as an access and with the help of standard surgical instruments. The proximal anastomoses after crossclamping of the aorta was sutured with conventional surgical instruments. End points of the prospective study were postoperative hospital stay, analgesic requirement, time point of postoperation oral feeding and ICU stay as well as ventilatory support. In addition, pre- and postoperative pulmonary function tests (FEV1, VC) were performed on the fourth postoperative day (statistical analysis by t-test, SPSS statistical package).
Results: There were no major complications in either group. Total operative time (225 ± 25 minutes) was significantly longer ($P<0{\cdot}02$) in the study group. There was a higher degree of pulmonary impairment in the conventional group compared to the laparoscopic group of patients. A regular diet could be resumed significantly earlier and patients were discharged sooner in the minimal invasive group. Patency rates did not differ in either group. Patients required significantly less analgesics when the laparoscopic technique was used.
Conclusion: We can infer from our data that using a video assisted technique the operative trauma as assessed by the postoperative course of patients is reduced. They benefit from less pulmonary impairment compared to a conventional procedure. This leads to a faster recovery and a shortened postoperative hospital stay. Therefore, this technique can offer a minimal-invasive alternative to endovascular procedures yet with well established long term results using standard vascular surgical techniques. The laparoscopic technique as such still requires significant improvements before a widespread use can be recommended.

Screening of Abdominal Aortic Aneurysms (AAA): a pragmatic approach

C. Kyriakides and N.R. Hulton *Department of Surgery, The Royal Oldham Hospital, Rochdale Road, Oldham, UK*

Aim: To evaluate the feasibility of a selective screening programme for AAA in men at the age of 65 within an urban setting and assess its impact on the expected increase in workload for the local hospital(s).
Materials and methods: 4823 men aged 65 were invited for ultrasound examination of the abdominal aorta between January 1993 and April 1997 as part of a General Practice based aneurysm screening programme covering two districts with a general hospital each. All examinations were carried out by senior radiographers using a portable B mode grey scale machine and a 3·5 MHz curvi-linear array probe. Patients with a maximum aortic diameter of over 3 cm were annually recalled, those with over 4 cm were referred to hospital for an outpatients appointment. Those with AAA greater than 5 cm were considered for surgery.

Results: 3497 (72·5 per cent) took part in the study, 1206 (25 per cent) did not attend and 120 (2·5 per cent) were excluded by their General Practitioners (GPs) on medical grounds. 3130 (89·5 per cent) had an aortic diameter equal or less than 2·5 cm and 196 (5·6 per cent) between 2·6 and 3·0 cm. 171 (4·9 per cent) had aortic diameters greater than 3 cm, 29 of whom had AAA greater than 5 cm with a mean diameter of 6·0 cm (range 5·1–9·0 cm). Of 127 with an initial diameter of 3·1–4·0 cm (mean progression in size of 2·3 mm/year) 22 enlarged to >4 cm and 3 to >5 cm. Of 24 with an initial diameter of 4·1–5·0 cm six enlarged to >5 cm. Sixty-nine (2 per cent) patients were referred to hospital. Eighteen underwent surgery, three are on the waiting list (one for endovascular repair) and one died (from rupture) while awaiting his operation. Five patients refused their operations and two failed to attend the clinic (all >5 cm) but remain well to date. No patient died following surgery.

Conclusions: Screening for AAAs in men aged 65 within an urban setting is feasible and well received by patients and GPs. Screening does not lead to a huge increase in terms of out-patient appointments and operations for AAA.

Graft dilatation following abdominal aortic aneurysm resection and grafting

A.F. Lennox, R. Englund, D.A. Robinson and K.C. Hanel
Vascular Surgery Department, St. George Hospital, Sydney, Australia

Dilatation of aortic prostheses following abdominal aneurysm surgery has been documented with both knitted and woven dacron grafts.

Aim: To review the experience in a single institution with both types of grafts, and to evaluate both rate and degree of dilatation, and association of dilatation with graft related complications.

Materials and methods: Between January 1987 and December 1992, elective repair of abdominal aortic aneurysm was undertaken in 219 patients. Of these patients, 146 had at least one follow-up ultrasound scan to evaluate their graft. These patients were analysed with respect to age, sex, size of initial aneurysm, type of graft used, time of follow-up and diameter of graft at follow-up scan. Any complications referable to the graft or recurrent disease was also documented at this time.

Results: A total of 216 scans were available for analysis. There were 123 male patients and 23 female patients in the group. The mean age was 72 years, and the mean preoperative aneurysm size was 5·8 cm. Thirty-four patients had a woven dacron graft inserted, while 112 were grafted with a knitted dacron prosthesis. Mean percentage increase in size for woven dacron was 17·3 per cent, while that for knitted dacron was 38·9 per cent (P<0·0001). Further analysis of the scans showed that the majority of dilatation occurred early, and the grafts were then relatively stable. No specific complications related to graft or anastamotic dilatation were noted.

Conclusions: Dilatation following implantation is a well known phenomenon affecting dacron, particularly in a knitted configuration. Some authors have suggested that graft dilatation is either an inherent failure mode of the material, or a precursor of more significant complications. This study contradicts this view, and dilatation was not associated with any adverse outcome. However, graft complications are known to be related to the weight of graft inserted, particularly in knitted grafts, and there is some question as to the dimensional stability in vivo of ultralightweight grafts. This raises concerns as to the behaviour of grafts inserted during endoluminal repairs and the possibility of late dilatation.

The endothelial response in thoracoabdominal aneurysm repairs

P. Lintott, H. Hafez, A.O. Mansfield, N. Cheshire, J. Wolfe and G. Stansby *Academic Surgical Unit, ICSM at St. Mary's, London*

Introduction: Reperfusion injury following major aneurysm repair is associated with postoperative complications including renal failure and adult respiratory distress syndrome and the endothelium is an integral part of their pathophysiology. Thoracoabdominal aneurysm repairs necessitate visceral reperfusion and have a high incidence of multi-organ failure. We investigated the enothelial response to thoracoabdominal aneurysm repair and its relationship to complications.

Methods: Plasma was collected from 16 patients undergoing thoracoabdominal aneurysm repair at incision, clamp placement, clamp removal, 30 minutes, 120 minutes and 24 hours. Soluble Intercellula Adhesion Molecule-1 (sICAM) was assayed in all patients by an ELIS technique and endothelin-1 (ET-1) was assayed in 12. These result were grouped by patient outcome. All results are expressed as median with 95 per cent confidence intervals (C.I.) and analysed with non-parametric tests.

Results: Serum concentrations of sICAM shows a significant decreas at 30 minutes 158 ng/ml (95 per cent C.I. 125–182 ng/ml) from incisio 240 ng/ml (95 per cent C.I. 201–304 ng/ml) P<0·01. At 24 hours thos patients that went on to develop complications had significantl increased their levels of sICAM; 366 ng/ml (95 per cent C.I 259–473 ng/ml) P<0·02, those who did not develop complications ha raised levels of sICAM that did not reach significance 312 ng/ml (95 pe cent C.I. 267– 357 ng/ml) P=0·06. ET-1 levels were significantl increased at two hours from baseline levels of <0·1 pmol/ (0–0·247 pmol/L) to 0·62 pmol/L (0·3–1·01 pmol/L) P<0·01. The rise di not correlate with outcome.

Conclusion: During aneurysm surgery the endothelial function i changed. The degree of endothelial damage may predispose the patient t serious postoperative complications.

Three years experience with endovascular treatment of aortic aneurysms

H. Oelert, W. Schmiedt, C. Düber, B. Eberle and M. Thelen
Klinik für Herz-, Thorax- und Gefäßchirurgie und Klinik für Radiologie der Johannes Gutenberg Universität Mainz
Langenbeckstr. 1, 55131 Mainz

Background: Three years after introduction of endovascular treatment aortic aneurysms there is still controversy, first of the high costs an second of the unknown durability of the graft.

Methods: From October 1994 until October 1997 a total of 42 aneurys were treated at our institution by endovascular prostheses, 38 abdomin aortic aneurysms (AAA) and four thoracic aortic aneurysms (TAA). Fi AAA were repaired by tube endovascular graft (Mialhe Stento Vanguard), in 33 AAA a bifurcated endovascular graft (Mialhe Stento Vanguard, Talent) was inserted. The procedure was performed in gener (n=9), peridual (n=12), and local (n=17) anaesthesia. Indications for TA endovascular treatment (what about the indications for AAA treatment were traumatic aortic ruptures (n=2), aneurysm with aortobronchial fistu (n=1), and aortobronchial fistula (n=1) 20 years after correction of aort coarctation.

Results: In AAA no conversion to open surgical treatment was nece sary. Mean hospital stay was five days. There were two proximal ar seven distal leakages as primary complications. Five leakages we treated by placing a second endovascular graft. One patient died on d four at home because of myocardial infarction. Late events were tw thrombotic graft occlusions, two secondary leakages, three graft disl cations and a few peripheral thromboembolic incidents. Correction graft failures was performed either by endovascular or surgical re-inte vention.

Conclusion: Presently endovascular treatment of aortic aneurysms limited to about 25 per cent of patients with AAA or TAA by morph logical reasons and high costs for the implant. Because of complicatio within the learning curve and unknown long-term results we changed a more differentiated indication, when and how to apply endovascul techniques. Placement of endovascular stent grafts is an elegant meth for the treatment of aortic aneurysm especially in the elderly with po condition.

The early complications of femorofemoral cross over grafts following endovascular repair of abdominal aortic aneurysms

S.R. Walker, B. Braithwaite, P.W. Wenham, S.T. MacSweeney, W.G. Tennant and B.R. Hopkinson *Department of Vascular and Endovascular Surgery, Queens Medical Centre, Nottingham, UK*

Aim: Of the three main methods of endovascular repair (EVR) of abdominal aortic aneurysms (AAA), aorta aortic graft, bifurcated graft and aorta uni-iliac graft, the latter has the potential disadvantage of requiring an extra anatomic bypass, i.e. a femorofemoral cross over graft, in order to maintain contra lateral pelvic and limb perfusion. The aim of the study was to assess the complications associated with the femorofemoral cross over graft following aorta uni-iliac EVR of AAA.
Method: A retrospective review of the complications attributable to the femorofemoral cross over graft in 136 patients having EVR of AAA with an aorta uni-iliac device.
Results: Following a median follow-up of seven months (range 0–36 months), four patients had superficial wound infections requiring antibiotic treatment and two patients had graft infections. There were seven (5 per cent) groin haematomas, six in patients with Dacron grafts. There was only one graft thrombosis.
Conclusion: The femorofemoral cross over graft is a safe and durable component of EVR of AAA with an aorta uni-iliac device against which complications of the bifurcated devices should be compared.

Renal complications following endovascular repair of abdominal aortic aneurysms

S.R. Walker, P.W. Wenham, W.G. Tennant, S.T. MacSweeney and B.R. Hopkinson *Department of Vascular and Endovascular Surgery, Queens Medical Centre, Nottingham, UK*

Introduction: Renal failure is a recognized complication of open repair of abdominal aortic aneurysms (AAA). Endovascular repair (EVR) of AAA has the potential to reduce this complication. The aim is to report the renal complications following EVR of AAA from a single centre.
Method: Prospective data collection on 164 pateints undergoing EVR of AAA. A history of renal failure and diabetes mellitus was recorded. Serum urea and creatinine levels were measured preoperatively and at regular intervals postoperatively. Renal impairment was defined as a serum creatinine greater than 130 μmoles/l.
Results: There was no significant difference in the pre and day one postoperative serum urea and creatinine levels. Fifteen patients had preoperative renal failure of which there have been seven deaths, four in the perioperative period. Of those patients with normal renal function preoperatively (n=149), four developed renal failure as part of multi system organ failure. Nine developed significant rises (20 per cent) in their creatine levels postoperatively when compared to preoperative values. Four of these nine patients have died, two in the perioperative period. There was no significant difference in the median contrast dose between those patients that did and did not have a deterioration in their renal function (300 mls vs 250 mls).
Conclusion: The incidence of renal impairment in those patients with originally normal renal function who go on to have EVR of AAA is 6 per cent. The mortality for those patients with known renal failure following EVR is high, 23 per cent in the perioperative period.

Adjuvant radiotherapy has no benefit after primary breast cancer treatment in selected postmenopausal patients

Th. Gruenberger, M. Gorlitzer, M. Mittlboeck, I. Axner, M. Rudas, D. Kandioler, S. Taucher, B. Gebhard, G. Steger, M. Gnant and R. Jakesz *Department of General Surgery, University of Vienna; Waehringer Guertel 18-20, 1090 Vienna*

The need of adjuvant radiotherapy after breast conserving surgery for localized breast cancer remains uncertain, especially in selected postmenopausal patients adjuvant irradiation may be spared.

We analysed 379 consecutive postmenopausal patients treated at our surgical department from 1983 to 1994. Surgical procedure was quadrantectomy and axillary dissection of level I+II in all patients. Only postmenopausal, lymph node negative patients with tumour diameter below 3 cm were included in this analysis. Half of the patients had adjuvant radiotherapy, the other part was not irradiated postoperatively. The influence of adjuvant radiotherapy on local recurrence free and overall survival was studied together with other prognostic factors both in univariate and multivariate manner.

Analysis of the tumour characteristics revealed 82 per cent of the patients having a tumour below 2 cm, 81 per cent had a well or moderate differentiated tumour and 78 per cent of the tumours were hormone receptor positive. After a median follow-up of five years adjuvant radiotherapy was unable to significantly reduce local recurrence free survival nor overall survival in this selected postmenopausal patients: 96 per cent of the patients without adjuvant radiotherapy and 98 per cent of the patients with radiotherapy were free of local recurrence (P=n.s.); overall survival was 89 per cent without radiotherapy vs 90 per cent in the irradiated group (P=n.s.). Multivariate analysis revealed none of the prognostic factors to be significant for local recurrence free survival; overall survival was found to be independently influenced by the receptor status (P=0·02).

In subgroup analysis of patients with hormone receptor positive tumours (250 patients) and those with adjuvant Tamoxifen therapy (181 patients) the local recurrence rate was under 3 per cent with or without adjuvant irradiation. In a prospective randomized trial of hormone receptor positive postmenopausal patients with different adjuvant hormone therapy after breast conservation we observed a local recurrence rate of 2 per cent with or without radiotherapy.

Therefore, we conclude that postmenopausal patients with positive tumour characteristics (Tu <3 cm, node negative, grading I or II, hormone receptor positive and adjuvant Tamoxifen therapy) have no benefit from adjuvant irradiation. A prospective randomized trial evaluating adjuvant radiotherapy in this patient group is currently in progress and we urgently await first results within the next years.

The specialist treatment of the axilla

*D.B. Kingsmore, †A. Ssemwogerere, †D. Hole, †C.R. Gillis and *W.D. George **University Department of Surgery, Western Infirmary, Dumbarton Road, Glasgow †West of Scotland Cancer Surveillance Unit, Ruchill Hospital, Glasgow*

Aims: Previous reports have highlighted both the survival advantage to treatment by larger specialist units and also the poorer survival associated with inadequate axillary treatment. This report compares the adequacy of treatment of the axilla by specialists and non-specialist units and the outcome of this treatment.

Methods: All 7144 histologically confirmed invasive breast cancers in women under 75 diagnosed from 1980–1994 who lived in a defined geographical area (population 1·5 million) were identified. The original pathology reports and 1950 out of 2531 case records for the years 1986–1991 obtained.

Results: Specialists compared to non-specialists performed no axillary surgery in 448 (19 per cent) vs 1705 (36 per cent); inadequate sampling in 136 (6 per cent) vs 1013 (14 per cent); sampled 4–9 nodes in 927 (39 per cent) vs 2301 (32 per cent); and 10 + nodes in 828 (35 per cent) vs 1313 (18 per cent); χ^2=10007·70, 4DF, P<0·00000. From the case records: specialists compared to non-specialists performed no axillary treatment in eight (1 per cent) vs 148 (15 per cent); sampled less than four nodes only in 40 (5 per cent) vs 115 (11 per cent); sampled less than four nodes in 12 premenopausal women vs 124 (5 per cent vs 40 per cent of all premenopausal women treated); did not remove any axillary nodes in an axillary sample in six (15 per cent of women with an axillary sample peformed) vs 51 (44 per cent). Axillary recurrence rates were noted in 24 (3 per cent) vs 84 (8 per cent).

Conclusions: Specialists examine the axilla more frequently, more thoroughly, omit axillary surgery only in very selected cases, and consequently had a recurrence rate almost one third that of non-specialists. Inadequate axillary staging may have resulted in inadequate local control but also in the omission of chemotherapy in younger women.

Treatment of local recurrence following breast conserving procedure

B. Márkus, G. Pintér and K. Széll *Surgical Department of Markusovszky Hospital, 9701 Szombathely, P.O. Box 143, Hungary*

Local recurrence following breast conserving procedure can be treated successfully. The clinical significance of local recurrence, influencing factors and the principal of treatment is under evaluation. The incidence rate, integration of risk factors (age, tumour size, lymph node status, completeness of excision, multicentricity) strategy of therapy and histomorphological signs all prove to be predictable in retrospective studies.

Between 1976 and 1995 there were 1312 operations carried out for the treatment of breast cancer in the Department of Surgery of the Markusovszky County Hospital. Out of these operations 260 breast conserving procedures were carried out. Thirty-two patients died, 22 of which had recurrence. In 10 patients with local recurrence mastectomy was performed, in six further patients re-excision was carried out and there is no data available for the remaining patients.

It is important to take into account the size of the tumour, the axillary lymph node status and the patient's age. Retrospective histomorphological evaluation performed in 15 patients – an intraductal component within the tumour exceeding 25 per cent, grading, ductal carcinoma in situ in the surrounding and an abnormal mitosis activity index – revealed either in all but one positive. Tumour free survival rate was lower following breast conserving procedures as opposed to mastectomies, however following adequate treatment of local recurrences there were no differences in the overall survival rate.

In the authors opinion in case of a local relapse after breast conserving treatment mastectomy should be chosen as long as there are no exact qualitative and quantitative histomorphological results available concerning the original tumour and its recurrence and no algorithm for the tests of prognostic markers is known. Should any late recurrence occur – after five years – with a slowly growing tumour smaller than 2·0 cm, repeated wide local excision is acceptable. Regular follow-ups – including mammography and clinical examination – are important following breast conserving procedures to detect and treat any local recurrences.

Angiotensin receptor expression and axillary node metastases in breast cancer

*A.J. Ogedegbe, *R. Inwang, †J. Puddefoot, †G.P. Vinson and *R. Carpenter **Breast Unit, St. Bartholomew's Hospital, West Smithfield, London †Department of Biochemistry, Queen Mary and Westfield College, London*

Angiotensin II (AII) is a biologically active peptide of the renin angiotensin system. Most of the known physiological actions of AII are mediated via its type I (ATI) receptor. AII regulates growth and development of tissues and thus may be an important factor in tumour progression. Using a specific monoclonal antibody we have previously shown ATI receptor expression in breast tissue.

Aims: The aim of this study was to extend our data and relate the expression of ATI receptor to disease progression and to determine quantitatively its relationship to factors known to have prognostic significance in breast cancer.
Methods: Formalin fixed paraffin embedded breast tissue sections from 151 women, aged between 22–84 years were examined by immunocytochemistry using the 6313G2 monoclonal antibody to the ATI receptor. A semi quantitative staining intensity index (SII) was used to determine the level of expression of the ATI receptor.
Results: Breast tissue from 151 patients were examined. breast cancers n=102 (67·5 per cent), benign breast disease n=47 (32·5 per cent). Of the breast cancers 37 (36·3 per cent) patients had metastatic axillary lymph node involvement. Semi quantitative analysis of the ATI receptor expression by SII revealed a range from 0·25–2·25. The mean score for receptor expression was higher in benign as compared to malignant breast tissue, but this difference did not reach significance (P<0·06). Analysis of the receptor expression in breast cancer showed no relationship with tumour grade but was shown to be significantly correlated with lymph node involvement (P<0·03).
Conclusions: The expression of ATI receptor appears to be higher in benign as compared to malignant breast tissue. Patients with axillary nodal involvement show a reduction in receptor expression compared to node negative patients, suggesting AII may be involved in breast cancer metastasis.

Outcome of inconclusive cytology in mammographically screen-detected breast lesions

M. Rashed, W.D. Thompson, J. Hoffman, A.L.G. Peel and D.J. Leaper *Departments of Surgery and Radiology, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK*

Aim: To correlate the cytological findings and radiological opinion with final histology of mammographically screen-detected breast lesions and to predict the likelihood of malignancy.
Materials and methods: Cytological and radiographic data were collected prospectively in 2137 women who had had fine needle aspiration (FNA) of mammographically suspicious breast lesion in a screening programme. These data were compared with the final histology of excised specimens.
Results: 192 (9 per cent) of the FNAs showed atypica (C_3) and 114 (5 per cent) high suspicion of malignancy (C_4). Of the C_3 lesions 88 (46 per cent) were benign and 104 (54 per cent) malignant (90 invasive and 14 in situ); and of the C_4 lesions 15 (13 per cent) were benign and 99 (81 per cent) malignant (85 invasive and 14 in situ); χ^2 32·8, P<0·001. Radiological opinion of the mammograms was graded R_1 (not malignant) or R_5 (malignant). When C_3 cytology and R_5 radiology were combined 56 of 65 (86 per cent) lesions were malignant; and when C_4 and R_5 were combined 52 of 53 (98 per cent) were malignant; χ^2, P<0·05.
Conclusion: FNA is widely used for exclusion or confirmation of malignancy in mammographically screen-detected breast lesions. When cytology is inconclusive the accurate prediction of malignancy can be improved by combination with radiological suspicion prior to definitive histological diagnosis.

Expression and clinical signification of lysozyme in male breast carcinoma

*C. Serra, †F. Vizoso, †E. Plaza, †J.C. Rodriguez, †L.O. González, †M.L. Lamelas and *A. Baltasar **Servicio de Cirugía General, Hospital 'Virgen de los Lirios', Alcoy 03804 Alicante, Spain †Servicios de Cirugía, Ginecología y Anatomía Patológica, Hospital de Jove, Gijón, Asturias, Spain*

Lysozyme is a major protein component of human milk. The object of this study was to evaluate the lysozyme tumoral expression and its clinical signification in 57 male patients diagnosed with breast carcinoma and without metastasis at the moment of diagnosis. Mean follow-up period was 41·3 months. Tumoral expression of lysozyme was evaluated by immunihistochemical methods, using antiserum against lysozyme and following the biotin-streptavidin method with the Supersentivie system (Biogenex, San Ramon, CA, USA).

A total of 35 tumours (61·4 per cent) stained negatively for lysozyme, one (1·75 per cent) carcinoma stained weakly positive, 14 (24 per cent) stained moderately positive, whereas the remaining 12 (21·05 per cent) tumours stained strongly positive for this enzyme. No significant correlation was found between lysozyme immunostaining and age of patients, tumour size, lymph node involvement, histologic grade or oestrogen receptor status. However, analysis of relapse-free survival (RFS) showed that high lysozyme values were significantly associated to shorter RFS periods (P<0·05). In addition, multivariate analysis according to Cox's regression model showed that tumoral lysozyme expression was an independent prognostic factor able to predict RFS (P<0·05).

These results led us to consider that lysozyme may represent a new prognostic factor able to identify subgroups of MBC patients with low or high risk for relapse and death.

Kidney tumours in children

V.K. Litovka, V.P. Kononuchenko, A.V. Scherbinin and I.P. Zhurilo *The Department of Children's Surgery of the Donetsk State Medical University, Ilyicha Avenue 16, Donetsk, 340003, Ukraine*

Aim: We assess 12-year experience of management of 81 children with kidney tumours.
Materials and methods: The patients' age ranged from 1 month to 14 years. The study population consisted of 39 boys and 42 girls. The benign neoformations were diagnosed in seven (8·6 per cent) cases. Seventy-four (91·4 per cent) patients had a malignant tumour. Right side localization of the tumour took place in 31 cases (38·3 per cent), left side – in 50 (61·7 per cent). Among the patients with malignant tumours nephroblastoma was diagnosed in all cases. The further management devised was taking into consideration general condition of the patients, the extent of tumour differentiation and process stage. Preoperative polychemotherapy were carried out. In all the cases operative treatment was used (transabdominal nephrectomy). Polychemotherapy, telegammatherapy as well as immunotherapy and phytotherapy were carried out postoperatively.
Results: Twenty patients (76·9 per cent) with I-II stage of the Wilms' tumour are living for 2–10 years. Among the patients with III-IV stage 16 children (33·3 per cent) are living. The others died against the background of an aggressive tumour and progression of the process. Only one patient with IV stage of the nephroblastoma are living. General mortality range was 55·56 per cent. Among benign neoformations (7 patients) were: teratoma (2), mesoblastical (2) and cystosis nephroma (1), disontogenical vessels tumour – fibrohaemangioma (1). Removal of benign neoformations in all cases resulted in recovery, there being neither complications nor recurrences.
Conclusions: Thus, the tumours of the kidneys in children are notable for a marked variety of morphologic structures of tumours and character of clinical manifestation.

Tumours and tumourlike formations of the great omentum in children

I.P. Zhurilo, V.K. Litovka, V.P. Kononuchenko and A.V. Scherbinin *The Department of Children's Surgery of the Donetsk State Medical University, Ilyicha Avenue 16, Donetsk, 340003, Ukraine*

Aim: Tumours and tumourlike formations of the great omentum occur rather rarely. The aim of the present study was to investigate variants of a clinical course and results of the given pathology treatment in children.
Materials and methods: From 1981 through 1997 21 children aged 3–14 years old having new masses of the given localization were treated in our clinic. The age of the majority of children (18 subjects, 85·7 per cent) did not exceed seven years and only in three cases made up nine years, i.e. 12 and 14 years old. Among all the patients 11 children had cysts (lymphangiomas), seven had verus tumours, one had a macro additional spleen of the great omentum and two had inflammatory pseudo tumours. Mesenchymoma (two cases), neuroblastoma, liposarcoma, lipoma, neurofibroma and teratoma were among solid tumours. Seventeen patients underwent a planned removal of the masses. Four children were operated on urgently. Technically the intervention was not difficult and consisted of resection of the great omentum within the intact tissues and removal of the cysts (tumours). The following histologic study testified the supposed diagnoses of the patients.
Results: Enlargement of the abdomen, a palpable tumourlike in the abdominal cavity, episodes of algesic attacks of a minor intensity and duration (12 children, 57·16 per cent) were characteristic of a noncomplicated course of the given pathology. A complicated course (nine children, 42·86 per cent) is characterized by an attack of pains in the abdomen which acquire a constant character and increase. The complication and suppuration of the cyst combined remind the acute appendicitis clinic. The follow-up of 20 patients is good. One child with liposarcoma died four months later following the operation due to dissemination of the process and an increase of tumour aggressiveness.
Conclusions: Thus, the tumours and cysts of the great omentum are notable for a marked variety of both morphologic structure of tumours and character of clinical manifestation. Because of the large size of omentum tumours a laparoscopic removal does not prove its value as the surgical technique relies on the penetration of a vacant abdominal cavity. The latter is inadmissible with the inflammatory character of these tumours. Besides the removal of the great omentum tumour, this must be followed by a thorough laparotomy to avoid metastases and by biopsy of enlarged lymph nodes.

The experience of our service in the use of the microsurgical free transfer performed on children

V. Al. Georgescu, O. Ivan, R. Onoe and C. Major *Clinic of Plastic Reconstructive Surgery, University of Medicine 'Iuliu Hatieganu', Spitalul Clinic de Recuperare, 3400 Cluj-Napoca, Str. Viilor Nr. 46-50, Romania*

General approach: The increasing number of children affected by various accidents resulting in complex traumas (usually with soft tissue losses) determined a proportional increase in the number of the treatment methods. One of the modern ways to face up such casualties is the use of microsurgical techniques.
Material and method: There are presented here eight cases – children aged between 4 and 12 years – in which we have performed: a great toe to thumb transfer; two transfers of radial forearm fasciocutaneous flaps; two transfers of latissimus dorsi muscle-cutaneous flaps; one transfer of muscle-cutaneous latissimus dorsi and serratus anterior flap; two transfers of osteo-fascio-muscular peroneal flap.
Results: For all the patients, the immediate evolution as well as the later one have been very good with the flaps' integration and morphofunctional recovery well achieved.
Conclusions: 1. There are certain situations when the free microsurgical transfer appears as the only logical method for covering certain complex and large soft tissue losses. 2. As for the subjects, the particularities linked to their age usually allow an evolution with no particular incidents, accidents or complications.

Individualized surgical strategy for hydatid cysts of the liver

P. Andronescu, A. Miron, S. Bacaliuc and L. Zarafin
N. Gh. Lupu Surgical Clinic, Sos. Stefan cel Mare 21, Bucharest, Romania

The timing and type of surgery to be performed for hydatid cysts of the liver depend upon the presentation as well as the number and position of the cysts. The present study analyses several operative solutions, ranging from simple closure to hepatic resection. In a five year period, from 1993 to 1997, 142 cases of hydatid cysts of the liver were operated. All cases had antibiotic prophylaxis but only 31 cases benefited from albendazole therapy.

After neutralisation and excision of the cyst, the residual cavity was treated conservatively or by resection. Conservative techniques consisted in: simple closure nine cases, Lagrot's procedure 31 cases, omental packing in eight cases, marsupialisation 16 cases and pericystodigestive anastomosis in 37 cases. Additional biliary drainage by T tube or biliodigestive anastomosis was used in 61 cases. Resectional techniques consisted in: left lobectomy seven cases, sectorectomy five cases, segmentectomy 18 cases, pericystectomy 10 cases, and wedge resection three cases. Additional biliary drainage was necessary only in seven cases. Overall postoperative morbidity was dominated by biliary leakage in 17 cases and residual abscesses in six cases.

Our experience might lead us to conclude that: 1. appropriate drainage of the residual cavity is the key to conservative procedures and 2. hepatic resection represents a simple solution whenever cyst localisation does not involve extended parenchymal sacrifice.

Malondialdehyde after normothermic liver ischaemia and antioxidant administration

H. Cerwenka, G. Khoschsorur, H. Bacher, G. Werkgartner, A. El-Shabrawi, F. Quehenberger, H. Rabl and H.J. Mischinger
Department of General Surgery and Institute of Med. Statistics, Karl-Franzens-University, Auenbruggerplatz 29, A-8036 Graz, Austria

Aim: To measure the increase of MDA-TBARS (malondialdehyde-thiobarbituric acid reactive substances) as a marker of lipid peroxidation after normothermic liver ischaemia in patients undergoing major liver resections and to evaluate the effect of an intraoperative antioxidant infusion.

Materials and methods: This prospective randomized study comprised 40 patients, 20 of them (treatment group) were given the antioxidant infusion containing tocopherol and ascorbate immediately prior to reperfusion onset. Venous blood samples for the determination of MDA-TBARS were taken prior to ischaemia, 30 minutes after reperfusion onset and at the end of the operation. Statistical evaluation was done by Mann–Whitney– Wilcoxon test. Preoperative liver function, the extent of the liver resections and the duration of ischemia were comparable in both groups.

Results: In the control group the mean value for MDA-TBARS was 0·70 nmol/ml (standard deviation SD=0·15): this rose to 0·87 (SD=0·27) during reperfusion. At the end of the operation it had returned to the basic level of 0·70 (SD=0·17). The difference between the pre- and post-ischemic values was statistically significant (P=0·01). In contrast, the treatment group showed only a marginal increase from 0·72 (SD=0·19) to 0·73 (SD=0·21) after ischaemia (P=n.s.): at the end of the operation the values were slightly lower than initially (0·68, SD=0·22). The exclusion of patients with advanced cirrhosis (histologically proven diagnosis) made the increase in the control group more obvious [from 0·70 (SD=0·14) to 0·97 (SD=0·23), P=0·007]. The differences in the increase of MDA-TBARS between the control and the treatment group then became even more statistically significant (P=0·007).

Conclusions: In our study MDA-TBARS were increased after normothermic liver ischaemia and this increase could be reduced by intraoperative administration of antioxidants.

Percutaneous treatment of hydatid cyst under sonographic guidance: preliminary study

C. Duta, Magda Pascut and D. Bordos *Second Surgical Clinic, University of Medicine and Pharmacy Timisoara Romania L. Rebreanu 156, cod 1900*

This paper is a retrospective study of the first 25 cases of hepatic hydatid cysts which underwent a conservative treatment between April 1996 – December 1997. There were 12 females and 13 males with a mean age of 40·1 years (7–65), which had 31 hepatic hydatid cysts. The cysts were classified in type I and II after Gharbi's classification. In the right liver lobe were located 23 cysts and in the left liver lobe eight cysts. In two cases a pulmonary hydatidosis was associated. Abdominal ultrasound and CT scan were routinely performed. All of these 31 cysts were treated by ultrasound guided fine-needle percutaneous puncture with aspiration and instillation of sterile alcohol 95. Pre and postoperative the patients were treated with Mebendazol. They were followed up by ultrasound and CT scan examination in the second day postoperative, at 1 week and monthly. No new cysts were noted during an average follow-up of 8·7 months and maximal cyst diameter decreased with minimum 62 per cent. A single episode of reversible anaphylaxis was encountered. The mean hospital stay was 3·3 days. In this paper the indications for conservative treatment and preliminary results of this method are discussed.

Prognostic significance of p53 protein and ki-67 antigen in resected liver metastases of colorectal cancer

P. Gervaz, A. Gavelli, C. Mainguene and Cl. Huguet *Service de chirurgie viscérale, CHPG, Monaco*

Aim: To determine whether p53 protein and ki-67 expression in liver metastases of colorectal cancer could predict outcome in patients treated by surgical resection.

Background: p53 tumour-suppressor gene mutation is a late event in colorectal cancer progression and correlates with metastatisation and poor prognosis. While liver resection can be performed safely, an accurate method of staging is required to compare the results of different treatment modalities after surgery. Analysis of genetic mutations may provide additional prognostic information and help the clinician in stratifying adjuvant therapy decisions.

Methods: monoclonal antibodies (DO-7 and MIB-1) were used to detect p53 nuclear protein and ki-67 antigen respectively in paraffin-embedded archival tumours of 46 patients with resected liver metastases. A comparison of survival was performed in different groups according to the level of staining of the two parameters.

Results: The median follow-up was 69 months. From the 46 studied liver tumour specimens, 36 (79 per cent) were found to present positive p53 staining. Considered alone, p53 overexpression was not a prognostic indicator of survival. When both parameters were analysed together, a subset of patients was identified with p53 and ki-67 minimal staining: 5-year survival in this group was markedly improved (53·3 per cent vs 11·5 per cent, log-rank test P=0·139).

Conclusion: 79 per cent of liver metastases expressed nuclear p53 protein: no statistical difference of survival was found between p53 positive and negative tumours. p53 negative tumours with low proliferative activity showed a trend toward improved survival.

Hepatic hydatidosis: postsurgical radiologic control: arguments for the conservative surgery

M. González Penabad, M. López Bañeres, A. Minguillón Serrano, F.J. Rebollo López, G. Martinez Sanz, J.J. Resa Bienzobas, MaC. Juyol Rodrigo, J.M. Del Val Gil and A. Bermejo Zapatero
Obispo Polanco General Hospital, Av. Ruiz Jarabo 5, 44002 Teruel, Spain

After conservative surgery in hepatic disease due to *E. granulosus*, there is a remaining cavity that can be quite large. Some authors have spoken about the 'residual cavity disease', referring to possible complications that can arise (bilomas, abscesses, exogen vesiculation).

Aim: To observe the volumetric evolution of the residual cystic cavity and the hepatic reexpantion after subtotal cystopericystectomy.

Material and methods: From January 1988 to December 1997, 80 cysts were operated on. Ultrasound was performed postoperatively to all patients when the drainage was purulent or bilious during more than seven days. The following ultrasound controls were done at third, sixth and ninth months and CT scan was done every year after surgery.

We consider incline cysts (IC), thinking in biped position, those in which its axis and horizontal conform an angle between 220° and 320°, semi-incline (SI) from 320° to 45° and 135° to 220°. Non incline (NI) cysts from 45° to 135°.

Results: Preoperatively mean longer diameter was 11·3 cm (4·5–27). According to CT scan after one year of surgery, the measures were: cysts lower than 10 cm (25 IC, 27 SI, 2 NI): 1·8 cm. Cysts which preoperatively diameter was between 10 and 15 cm (6 IC, 4 SI, 10 NI): 4·1 cm. Those with longer diameter bigger than 15 cm (3 IC, 3 SI): 7·8 cm.

The residual cavity reduction after surgery was 90 per cent for the cysts lower than 10 cm; 75 pr cent in those between 10 and 15 cm; and 60 per cent in cysts longer than 15 cm. There are no relapses of the parasite in the cysts cavities.

Conclusions: 1. Natural progress of the residual cavity is to involution at the same time that hepatic parenchima expands. 2. SCP is a good procedure avoiding sacrificing healthy parenchyma.

Laparoscopic liver resection compared with conventional partial hepatectomy

B. de Hemptinne, U.J. Hesse, P. Pattyn, R. Troisi and M. Takkal *Department of Surgery, University Hospital, De Pintelaan 185, 9000 Ghent, Belgium*

Laparoscopic liver resection is technically possible, but at present careful patient selection is required. Tumour size and location are of major influence on the feasibility of a laparoscopic operation. Peroperative echography is essential in the decision making. Isolation and ligation of blood vessels and bile ducts during transparenchymal liver dissection must be performed with a proper visual control of the operating field.

We carried out laparoscopic liver resection with the ultrasound dissector in three patients. In a matched-pair analysis of retrospective data the results were compared to patients undergoing conventional hepatic resection of equivalent lesions. In one patient conversion of laparoscopic to open surgery was required. As expected, the beginning of the learning curve was responsible of a prolonged duration of operative time for the resection in the laparoscopic operated patients. Patients of the laparoscopic surgery were discharged from the hospital at five and six days when patients undergoing conventional operation after a mean of 12±5 days.

Conclusion: Laparoscopic liver resection is feasible and can be considered the first choice in some peripherically located benign lesions.

Hepatic resection and transplantation for hilar cholangiocarcinoma

S. Iwatsuki, S. Todo, J.W. Marsh, J. Madariaga, R.G. Lee, I. Dvorchik, J.J. Fung and T.E. Starzl *Falk Clinic, 3601 Fifth Avenue, 4th Floor, Pittsburgh, PA 15213*

Aim: This retrospective study was undertaken to evaluate various pathological risk factors which influence the survival of patients with hilar cholangiocarcinoma after curative hepatic resection and transplantation.

Due to the rarity of this malignant tumour, its prognostic risk factors have not been sufficiently analysed in any previous reports. As such, the paucity of survival data has not previously allowed stratification by pTNM staging sufficient for the evaluation of its reliability.

Methods: During the 15 year period, 72 patients (43 males and 29 females) with hilar cholangiocarcinoma underwent hepatic resection (34 patients) or transplantation (38 patients) with curative intent. Medical records and pathological specimens were reviewed to examine the various prognostic risk factors for survivals. Survival was calculated by the method of Kaplan–Meier using the Log Rank test with adjustment for the type of surgery.

Results: 1-, 3-, and 5-year survivals after hepatic resection were 74 per cent, 38 per cent, and 10 per cent, respectively and those after transplantation were 60 per cent, 32 per cent, and 25 per cent, respectively. Univariate analysis revealed that T-3, positive lymph node, positive surgical margins, and pTNM stage III and IV were statistically significant poor prognostic factors. Multivariate analysis revealed that pTNM stage 0, I and II, negative lymph node, and negative surgical margins were statistically significant good prognostic factors.

For the patients in pTNM stage 0-II, 1-, 3-, and 5-year survivals were 80 per cent, 73 per cent, and 73 per cent respectively. For patients in pTNM stage IV-A with negative lymph nodes and surgical margins, 1-, 3-, and 5-year survivals were 66 per cent, 37 per cent, and 37 per cent, respectively.

Conclusion: Satisfactory long-term survivals can be obtained by curative surgery for hilar cholangiocarcinoma with hepatic resection and liver transplantation. pTNM stages III and IV-A should be reconsidered.

Hepatic resection for non-colorectal and non-neuroendocrine liver metastases

C. Laurent, E. Rullier, J. Carles and J. Saric *Department of Digestive and Hepatobiliary Surgery, Saint-André Hospital, 33075 Bordeaux, France*

Aim: The resection of liver metastases, which is most commonly performed for colorectal metastases, provides a 5-year survival of 20–30 per cent. Because of heterogeneity of noncolorectal (NCR) metastases, outcome of resection of NCR liver metastases is unknown. The aim of this study was to evaluate survival of patients undergoing hepatic resection for NCR and non-endocrine liver metastases.

Methods: From 1980 to 1997, 254 patients underwent hepatic resection for liver metastases. Thirty-three patients (13 per cent) had curative resection for NCR and non-endocrine liver metastases and form the basis of this study. There were 21 men and 12 women, with a mean age of 53 years (range 24–82). The primary tumour was digestive (n=12), genitourinary (n=11), and other (n=10). The mean number (1·9; range 1–6) and the mean size (49; range 10–100) of the liver metastases did not differ among the three groups. In the 33 patients, 36 hepatic resections were performed (three iterative resections). Eighteen patients underwent major hepatectomy (15 right, three left) and 18 patients had minor hepatectomy (nine bisegmentectomies, six segmentectomies and three wedge resections). In six cases, resection of liver metastases was associated with concomitent resection of primary tumour: pancreatectomy three, gastrectomy two, enterectomy one.

Results: There was no postoperative mortality. Morbidity occurred in three patients (8 per cent): anastomotic oesojejunal fistula, colonic fistula and hepatic failure. The actuarial survival of the overall population at 1, 3 and 5 years was 76 per cent, 36 per cent and 28 per cent respectively. The median survival was 18 months for digestive tumours, 30 months for genitourinary tumours and 24 months for the other tumours.

Conclusion: Our results showed that curative resection of NCR and non-endocrine liver metastases allows the same survival as resection of colorectal liver metastases. However, survival depends on the primary tumour and most prolonged survival are in patients with genitourinary liver metastases.

Surgical treatment of liver trauma: our experience on 51 patients

I.A. Muttillo, M. Cardi, A. Brandimarte, A. Barbarosos, R. Maira and A. Bolognese *I Istituto Clinica Chirurgica, S.S. Chirurgia Urgenza 3, Università di Roma 'La Sapienza' 00161 Rome, Italy*

In patients undergoing laparotomy for abdominal trauma, liver injury is present in 15 to 20 per cent of those with blunt injury, and 40 per cent of those with stab wound. Mortality after major liver trauma ranges from 20 to 60 per cent with postoperative complications occurring in up to 40 per cent of the patients. The aim of this study was to evaluate the results after surgical treatment on a series of 51 patients admitted and treated in our Institution for hepatic trauma. Trauma was penetrating in 16 (gunshot wound in nine and stab in seven) and blunt in 35 patients (motor vehicle accident in 27, other causes in eight). According to Moore classification, 12 (23·5 per cent) were grade I, seven (13·7 per cent) grade II, 19 (37·3 per cent) grade III, seven (13·7 per cent) grade IV, and six (11·8 per cent) grade V. All patients with penetrating trauma underwent surgery. Of the others, 11 were operated in emergency for presence of shock. The remaining 24 haemodynamically stable patients underwent diagnostic peritoneal lavage (DPL), sonography, CT scan and angiography (only in selected cases). Seven had a positive tap at DPL and CT scan confirmed III, IV and V grade injuries and were operated on. Of the 17 others with negative DPL, CT scan showed grade I, II and III liver injuries in 11 patients which had a conservative approach, while six with grade III, IV and V injuries after initial conservative approach, had to be operated on. Surgical treatment was in 25 patients (71·4 per cent) debridement and suture, in six patients (17·2 per cent) minor liver resection and in four (11·4 per cent) left hemiepatectomy. No deaths were observed in grade I and II trauma, while three over 19 patients died in grade III (15·8 per cent), five over seven in grade IV (71·4 per cent) and all the six patients with grade V (100 per cent). From the results of our study it can be concluded that DPL is oversensitive in the detection of small intraperitoneal blood collections, while CT scan had higher specificity and sensibility both in the evaluation and monitoring of hepatic trauma.

Qualification for liver resection using laparoscopy and intraoperative laparoscopic ultrasonography

M. Słupski, W. Szczesny, W. Hryncewicz and W. Zegarski *The Ludwik Rydygier Medical University in Bydgoszcz, Department of General and Vascular Surgery, ul. M. Skłodowskiej-Curie 9, 85-094 Bydgoszcz, Poland*

Total estimation of cancer advancing is often done just during laparotomy. Laparoscopy connected with laparoscopic intraoperative ultrasonography (LIOUS) let us for detail estimation of cancer spreading in peritoneal cavity organs. We introduced this method in our Department in cases with liver tumours both primary and metastatic. From March to December 1997 16 patients have been done LIOUS after general anaesthesia just before laparotomy (10 metastatic after colon and rectum surgery, six with primary changes). In four cases among 10 patients with metastases laparotomy were not done due to dissemination of the cancer. Remains six were radically operated. In the group of six cases with primary changes in two patients we found hemangioma of the liver and in four hepatoma (two of them were resectable). In every case intraoperative histopathological examinations were done.

Conclusions: Laparoscopy with LIOUS lets us precisely estimate possibility of radical treatment of tumours in the liver.

Resection of metastatic colorectal liver cancer: preliminary results of a single centre experience

R. Troisi, U.J. Hesse, B. Jacobs, D. Van de Putte, *M. Hautekeete, *H. Van Vlierberghe, †M. Praet, ‡L. Defreyne, P. Pattyn and B. de Hemptinne *Department of General, Abdominal and Transplant Surgery, *Gastroenterology, †Pathology, ‡Radiology, University of Ghent, De Pintelaan 185, 9000 Ghent, Belgium*

The consensus in the treatment of liver metastasis from colorectal cancer is that solitary and also multiple lesions should be resected to improve prognosis. However, a potentially curative treatment is applicable to only 10–20 per cent of all patients affected by metastatic colorectal liver cancer. We retrospectively analysed our experience focusing on surgical management and predicting factors affecting the survival of colorectal metastases.

Methods: Thirty-four patients with colorectal liver metastases underwent major, minor and atypic liver resections during a period of six years. There were 20 males and 14 females with a mean age of 57±10 years (range 39 to 74). Nineteen patients (56 per cent) underwent trans-arterial chemoembolization (TAE) before liver resection. Our study was focused on: type and stage of primary tumour; number, size and type of liver metastasis; surgical technique; resection marges; node involvement; total time of Pringle manouvre; blood transfusions; postoperative recovery and oncologic follow-up. Tumours were single in 23 and multiple in 11 patients (range 1 to 5) with a mean size of 4·9±2·9 cm (range 1·2 to 13 cm). Types of liver resections were: 12 Right Hepatectomy (RH); 3 Extended RH; 2 Left Hepatectomy (LH); 4 Extended LH; 2 Trisegmentectomy; 4 Bisegmentectomy and 7 Atypical Resections. Three patients underwent re-resections (8 per cent).

Results: No perioperative mortality was seen and no postoperative bleeding episodes were encountered. Postoperative complications were recorded in 14 patients with a total morbidity rate of 41 per cent. There were 10 cases of pleural effusion; 2 cases of atelectases with pneumonia and 2 of biliary leakage. Sixteen patients had a recurrence in the liver for a total recurrence rate of 47 per cent. Prognostic factors leading to recurrence were represented only by positive tumoral resection margins. There was an influence of type of resection (major vs atypic), number of tumours and blood transfusions on overall patient survival, however statistically not significant. In TAE group 35 per cent with high necrosis rate were noticed, however statistically not significant. Mean survival after surgery is 30 months (range 6 to 73). Overall actuarial survival is 96 per cent, 60 per cent and 23 per cent at 1, 3 and 5 years and disease-free survival at 1 and 3 years is 88 per cent and 54 per cent respectively.

Conclusions: 1. The disease-free survival is affected only by positive resection margins. Other prognostic factors such as above mentioned could, however, statistically influence the prognosis in a large patient population. 2. Preoperative TAE does not improve long-term results despite high-percentage of tumoral necrosis. 3. Long-term survival can be accomplished in selected patients if hepatic resection can be performed with reasonable risk.

Hepatic trauma: conservative treatment

Cl. Turculet, Gh. Ionescu, Al. Bucur, St. Jianu, Ileana Racoveanu, M. Avram and B. Gaspar *Clinic of Surgery, Emergency Hospital Bucharest, Romania*

Between 1993–1997 in Bucharest Emergency Hospital were admitted and treated 221 patients with hepatic trauma; 173 (78·2 per cent) were consecutive to blunt abdominal trauma and 48 (21·7 per cent) to penetrating injuries.

The main causes leading to these trauma were: traffic accidents – 125 (56·5 per cent), (self) aggressions 68 (30·7 per cent), falls 20 (9 per cent), accidents during work eight (3·6 per cent).

Conservative treatment was applied to 66 (29·86 per cent) patients: among them, 60 (90·9 per cent) had grade I or grade II hepatic injuries.

Laparotomy was however necessary for 29 (43·9 per cent) of these patients, imposed by other abdominal injuries such as: spleen, colon, small intestine, diaphragm, etc.

There were 13 deaths (19·6 per cent) none of them being caused directly by the liver injury.

The criteria for a conservative treatment in heaptic trauma were: a) absence of peritoneal irritation at repeated clinical examination of the abdomen (performed by experienced surgeons); b) absence of major haemoperitoneum at repeated CT scanning and c) haemodynamic stability.

A developing useful criteria was in our experience the exploratory laparoscopy used for six (9 per cent) cases with multiple trauma and positive peritoneal lavage; in such cases we experienced with other patients that transportation for CT scanning could deteriorate the haemodynamic stability.

Laparoscopic vs open appendectomy for acute appendicitis: a prospective randomized trial

M. Birth, I. Witten, E. Gadzepko and H.-F. Weiser *First Department of General, Viszeral and Thoracic Surgery, Diakonie-Hospital, 27342 Rotenburg/Wümme, Germany*

Aim: The discussion about laparoscopic appendectomy has increased since introduction of MIS. To compare the laparoscopic with the open technique for acute appendicitis a prospective randomized trial was performed.
Materials and methods: 200 consecutive patients with a diagnosis of acute appendicitis were randomized to either laparoscopic (n=100) or open appendectomy (n=100) between February 1995 and November 1997.
Results: Both treatment groups were comparable in age, sex, BROCA index, previous abdominal surgery and the histological classification of appendicitis. The diagnosis of acute appendicitis was confirmed by laparoscopy in 90 patients and by laparotomy in 88 patients. Conversion from laparoscopic to open appendectomy was necessary in five patients (5 per cent) for an appendix that could not be mobilized (4) and an unsuspected small bowel perforation by a foreign body in one case. When compared to open appendectomy the laparoscopic group had more additional lesions which were discovered intraoperatively besides appendicitis (24 per cent vs 7 per cent) and shorter hospital stay (median stay: 7·54 vs 8·81 days). No statistical differences could be found with respect to wound infections (7 per cent vs 11 per cent), general complications (2 per cent vs 2 per cent), mean operating time, postoperative pain score and requirement for pain medication.
Conclusions: Under trial conditions laparoscopic appendectomy is as safe as open appendectomy. Besides the diagnostic aspect it does not provide significant advantages.

Appendicular peritonitis: laparoscopic approach in 58 patients

J.L. Bouillot, K. Aouad, B. Alamowitch, P. Sellam, J. Fourmestraux and J.P. Bethoux *Department of Digestive Surgery, Hôtel Dieu, 1 Place Parvis Notre Dame, 75004 Paris, France*

Aim: The use of laparoscopy in case of acute appendicitis is still debated. We prospectively studied the benefits of a laparoscopic approach in case of complicated appendicitis with localised or generalised peritonitis.
Materials and methods: Between January 1993 and December 1997, 552 consecutive patients (patients) have been operated by laparoscopy for acute appendicitis. Among them, 58 patients presented with a peritonitis assessed by peroperative inspection, bacteriological sample and histological exam. It concerned 41 males and 17 females, mean age 37·4 years (extremes: 18–85 years); 85 per cent were classified ASA I. Surgical treatment was realised by 10 surgeons. After abdominal exploration and peritoneal lavage, a totally 'in' appendectomy was performed if it was judged technically possible.
Results: There were 36 local peritonitis (LP) and 22 generalised ones (GP). A totally laparoscopic management was possible in 34 patients (58·6 per cent) with a mean operative time (MOT) of 93 minutes. A conversion was necessary in three cases of GP (median route in two cases, Mac Burney incision in one case), in 21 cases of LP (median route in two cases) with an MOT of 108 minutes. There was no mortality in this series. Postoperatively, 11 patients presented complications (three febrile ileus, six intraperitoneal abscesses necessitating reoperation in four cases, parietal abscess in two cases). The mean operative stay (MOS) was seven days (extremes: 3–21) in absence of conversion and 12 days after conversion.
Conclusion: Our results suggest that laparoscopic treatment of appendicular peritonitis in adults is possible but difficult. It is particularly recommended in generalised peritonitis allowing in 86·3 per cent of patients an extensive peritoneal lavage and appendectomy, avoiding a large median incision. Appendicular abscess is more difficult to manage by such laparoscopic approach necessitating conversion in 58·3 per cent of patients, but usually via a right iliac incision.

Management of retroduodenal perforations complicating endoscopic sphincterotomy (ES)

S.V. Berdah, J. Guiramand, P. Orsoni, M. Barthet, J.C. Grimaud and R. Picaud *Department of Digestive Surgery, Hopital Nord, Chemin des Bourrelly, 13915 Marseille Cedex 20, France*

Aim: Management of retroduodenal perforation (RDP) is controversial. The aim of this retrospective study was to report our experience in the treatment of RDP.

Material and methods: From April 1996 to September 1997, 488 ES were performed consecutively. During this period, seven RDP (1·4 per cent) were detected in five women and two men of median age 82 years (52–86). The diagnosis of RDP was made either readiologically during the procedure (five cases), either clinically the day after the ES (abdominal pain: one case; temperature: one case). Nonoperative treatment (gastric tube, antibiotics, total parenteral nutrition) was initially undertaken. Surgery was indicated in case of persistence or aggravation of clinical signs[1].

Results: Medical treatment was successful in 4/7 cases. Emergency surgery was indicated in 3/7 cases for: sepsis (two cases), abdominal pain (one case); one patient deceased postoperatively at day six because of massive haemorrhage. Moreover, in three out of the four patients non-operatively treated, elective surgery for the initial disease was performed, less than 30 days after the perforation: pancreatoduodenectomy for pancreatic adenocarcinoma (six days after the RDP), repair of choledocoduodenostomy (19 days after the RDP), cholecystectomy for biliary lithiasis (29 days after the RDP). In total 6/7 patients had abdominal surgery (emergency: three cases, elective: three cases); there were no operative findings in 4/6 patients; 1/6 patient, operated on for abdominal pain, had retroduodenal biliary infiltration without macroscopic perforation; 1/6 patient, operated on for sepsis, had gross perforation repaired by interrupted suture and placement of retroduodenal drains, but deceased postoperatively.

Conclusions: RDP is not systematically associated with operative findings. Surgical treatment of RDP should be indicated on the basis of clinical criteria.

[1] Chung et al. Am Surg 1993; 165: 700–703.

Finney pyloroplasty: a reasonable alternative

K. Daskalakis, S. Kapiris, C. Kounoudes, D. Papoutsas and E. Tsepetis *Third Surgical Department, Evangelismos Hospital, Ipsilantou 45 st. 10676 Athens, Hellas*

Aim: The aim of this study is to present our experience in performing Finney pyloroplasty plus truncal vagotomy as an alternative to Heineke-Mikulicz pyloroplasty plus truncal vagotomy for the managing of duodenal ulcers.

Materials and methods: In the last 10 years (1986–1996), 335 patients (243 males, mean age 57·2 years and 92 females, mean age 60·4 years) underwent truncal vagotomy accompanied by pyloroplasty for the treatment of duodenal ulcer or its complications. Finney pyloroplasty was performed in 63 patients (47 males, mean age 56·7 years and 16 females, mean age 59 years). Twenty of the operations performed for bleeding, 12 for perforation, eight for pyloric stenosis and 23 for the treatment of uncomplicated ulcer. Heineke-Mikulicz and Jaboulay pyloroplasty were performed in 263 and nine patients respectively. The choice of the pyloroplasty was made liberally according to the surgeon`s preferences.

Results: There were no major postoperative complications after Finney pyloroplasty. Postoperative mortality was nil. Although there were no specific indications to perform Finney instead of Heineke-Mikuliez pyloroplasty, we found interestingly convenient: 1) to cover the crater of a large posterior bleeding ulcer using the upper segment of the posterior wall of the Finney pyloroplasty; 2) to manage pyloric obstructions with major deformity of the area; and 3) to bypass difficulty treated post-bulbar ulcers. The main disadvantage of the technique is the difficult management of the duodenal sump in case of future gastrectomy.

Conclusions: We concluded that Finney pyloroplasty is a reasonable alternative to Heineke-Mikuliez pyloroplasty especially in managing bleeding posterior ulcers and post-bulbar ulcers.

Long-term parenteral nutrition (TPN) for short-bowel syndrome: 18 years of experience

M. Gawenda and Th. Schmitz-Rixen *Department of Visceral and Vascular Surgery, University of Cologne, Joseph-Stelzmann-Straße 9, D-50931 Cologne, Germany*

Bowel infarction by mesenteric vascular occlusion is often regarded as a fatal disease. Often the diagnosis of severe bowel ischemia is made during laparotomy, and then ended as exploratory laparotomy. In such case the mortality rate is 100 per cent. If radical resection therapy is carried out even at the site of almost complete small bowel infarction, survival can be achieved in some patients. The motivation to attempt treatment should be further enhanced by the observation that short bowel disease can be successfully treated, giving an acceptable quality of life for the patients.

Between 1 January 1979 and 30 September 1997 we treated 24 patients (2 patients < 1 year, 22 patients > 1 year) with short bowel syndrome (mean length of small gut 34 cm) caused by mesenteric occlusive disease; their age ranged between 4 and 78 years, and the total duration of parenteral nutrition was more than 41 000 patient-days. With a median of 1890 days, the longest individual period of parenteral nutrition was 6002 days. We show the problems of long-term parenteral nutrition, including the catheter (Type Broviac) associated and nutritional complications, with reference to the individual course of the patients.

Despite described problems, patients of all ages can return to near-normality with an acceptable quality of life with the aid of parenteral nutrition at home.

Perforated duodenal ulcer: results after emergency treatment

I. Gil, J. Deus, D. Guemes, M.S. Moreno, R. Palacin, F. Burdio and L.S. Torca *Department of Surgery, University Hospital, Zaragoza Av. san Juan Bosco 15, 50010 Zaragoza, Spain*

Background: The number of surgical procedures for a complicated peptic ulcer disease has fallen since the introduction of the H2 antagonists and omeprazole, nevertheless several studies have demonstrated that the number of surgical procedures due to complicated peptic ulcer disease remains stable in the last years. It is accepted that 4 per cent to 5 per cent of the active peptic ulcers will perforate during its evolution. These ulcers still have a high mortality rate (average 10 per cent), depending mainly on its presentation and surgical procedure.

Aim: This is a retrospective study of our experience in the treatment of perforated peptic ulcer. We intend to establish a protocol of treatment and follow-up in order to reduce mortality and relapse of the ulcer.

Material and methods: Between January 1984 and December 1995, 100 patients having an acutely perforated peptic ulcer were operated at our institution. We considered only duodenal or prepiloric ulcers, gastric ulcers or those located beyond the third portion of the duodenum were not reviewed. Mean age was 53 years (range 17–94). We analysed morbidity, operative mortality, relapse of the peptic disease and sequelae. χ^2 was used as statistical analysis.

Results: 54 patients underwent truncal vagotomy and pyloroplasty (TVP), 35 patients were treated with simple closure of the ulcer and 11 patients underwent other different procedures. Eleven patients died (mean age 72 years, range 55–84, seven males and four females) nine of them suffered hypovolemic shock before the operation, two had a previous partial gastrectomy, nine had a previous peptic ulcer surgery (seven simple closure of a perforated ulcer, two TVP). Prognostic mortality risk factors were: age >70 years, interval between symptoms and surgery >24 h and hypovolemic shock at the time of diagnosis ($P<0{\cdot}001$). Morbidity was high (17 per cent) (wound infection, respiratory distress, pneumonia, prolonged gastric emptying). Mean follow-up was five years (range 2–7). 12 per cent of the cases relapsed, 20 per cent of the patients treated with simple suture ($n=7$) and 2 per cent of the patients treated with TVP ($n=5$).

Conclusions: 1) Worsened prognosis: patients aged >70 years, patients clinically diseased 24 h before the operation and patients suffering hypovolemic shock. 2) In the presence of risk factors major operations should be avoided (TVP), simple suture could be the proper procedure.

Sonographic diagnosis of Crohn's disease of the small bowel

Z. Tarján, E. Makó, T. Dévai, L. Duffek, Z. Vígváry and G. Tóth
Department of Radiology, Semmelweis Medical University, Ulloi ut 78/a, 1082 Budapest, Hungary

Aim: To evaluate the diagnostic accuracy of high-resolution graded compression ultrasound (GrUS) compared to enteroclysis, CT and immunoscintigraphy in small intestinal Crohn's disease (SICD).
Materials and methods: GrUS was performed in 250 patients with suspected Crohn's disease of the small intestine. The results were compared to enteroclysis, small bowel CT and 99mTc AgAb immunoscintigraphy.
Results: 184 patients proved to have SICD with enteroclysis and clinical tests. The sensitivity, specificity and accuracy of GrUS were 87 per cent, 92 per cent and 89 per cent respectively. False negative GrUS studies occurred only in early disease. Enteroclysis was more accurate, CT was more sensitive, but less specific, immunoscintigraphy had less sensitivity. In early disease (n=51) enteroclysis and immunoscintigraphy had higher sensitivity, whereas the sensitivity of GrUS and CT decreased. In advanced and active disease abscesses were detected by CT and GrUS more frequently than with enteroclysis. GrUS detected all significant luminal strictures, only smaller narrowings were missed, compared to enterolclysis. Active and inactive fistulas were both reliably demonstrated by GrUS. In detecting lymphadenopathy GrUS was superior to CT. The different gut wall layer patterns, demonstrated by GrUS, correlated well with the disease severity.
Conclusions: The diagnostic results of GrUS are similar to those obtained by CT and immunoscintigraphy. However, in early stages, enteroclysis and immunoscintigraphy are more sensitive. GrUS has the possibility to stage the disease and to detect surgical indications, thus the decision of surgical intervention can be made and the effect of the therapy could be followed without endoscopy or enteroclysis.

The addition of barium does not improve the quality of water soluble contrast radiology in adhesive small bowel obstruction

B.P. Waxman, R. Szabo and S. Bell *Academic Surgical Unit, Monash University, Dandenong Hospital, P.O. Box 478, Dandenong, Victoria 3175, Australia*

Water soluble contrast (WSC) meal and follow through radiology can be diagnostic, therapeutic, and a predictor of the need for surgery in the management of adhesive small bowel obstruction (SBO)[1].

The aim of this study was to determine whether the addition of barium improves the quality of radiographs and could better predict the level of obstruction.

A prospective study was conducted on patients presenting with SBO having had previous abdominal surgery. They were randomized to receive either 120 ml of WSC (Gastrograffin®) (Group A) or 100 ml WSC plus 20 ml of dilute barium (Group B). Plain supine abdominal radiographs were taken at 1, 2, 4 and 6 hours, as part of a meal and follow through procedure. SBO was defined as a failure of contrast to reach the caecum at 4 hours. The clinical outcome was determined by the consultant surgeon.

The radiographs were assessed by two radiologists independently, blinded to the diagnosis and clinical outcome, and a numerical score determined using criteria for quality and level of obstruction.

Forty seven patients were randomized between September 1996 and November 1997. The radiology scores for the two groups were similar, Group A: (n=25) median = 13, range: 7–22 and Group B: (n=22) median = 13, range: 8–22. Thirteen went on to surgery, eight having adhesive SBO, four in each group. The level of obstruction found at surgery was no better predicted in Group B.

The addition of barium neither improves the quality nor the predictability of level of obstruction in the management of SBO.

[1] Chung, C.C., Meng, W.C.S., Yu, S.C.H. et al. A prospective study on the use of water-soluble contrast follow-through radiology in the management of small bowel obstruction. A.N.Z.J. Surg. (1996) 66: 598–601

Open splenectomy: is this still a valid therapeutic option?

P. Chirletti, R. Caronna, P. Sammartino, *A. Testi, *A. Amendola, A. Bovino, E. Naticchioni and V. Stipa *Surgical Phatology IX, Surgical Clinic I, *Hematological Department, University of Rome, 'La Sapienza', V. del Policlinico, 00161 Rome, Italy*

Aim: Growing interest has recently centred on laparoscopic splenectomy for the treatment of idiopathic thrombocytopenic purpura and spherocytosis. Among points needing further discussion are the duration of the laparoscopic procedure, postoperative morbidity and mortality and long-term results, especially in children. In this retropective study we reviewed the outcome in a series of open splenectomies and compared our results with those from reported series.

Material and methods: During the 10 years from 1987 to 1997 a total of 184 patients underwent open splenectomy; 78 had malignant hemolymphopathies and 106 had thrombocytopenic purpura or spherocytosis. Of these 106, 70 (66 per cent) were younger than 14 years old. In the 106 patients who underwent splenectomy for idiopathic thrombocytopenic purpura or spherocytosis we assessed the following variables: operative time; blood loss, transfusional requirements, morbidity and mortality, length of hospitalization and long-term outcome.

Results: Operations lasted a mean 90 minutes (range 60–120 minutes); blood losses never exceeded 150 cc and no patients needed intraoperative blood transfusions. Platelet transfusions were needed only preoperatively in patients at high risk of hemorrhage (platelets <30 000 mm^3, bleeding time >15 seconds in non-responders to preoperative immunoglobulin therapy). Mortality was nil. Morbidity in children was accounted for by minor complications (wound infections or slight pleural effusions) and in adults one case only (2·7 per cent), who had an unsuccessful splenectomy, showed a hemothorax following a thoracocentesis performed for a left pleural effusion. This was the only patient who needed a blood transfusion. The postoperative hospital stay lasted a mean nine days long-term follow-up (median 53·3 months, range 2–120) only one patient (2·7 per cent) had a laparocele. 20 per cent of the adults and 14 per cent of the children with idiopathic thrombocytopenic purpura had recurrent disease.

Conclusions: Our review shows that open splenectomy can achieve extremely satisfactory results: our patients had far better outcomes than published series (reported morbidity 6–20 per cent, intraoperative blood loss 300–500 cc and transfusional requirement 13 per cent). The good outcome after open splenectomy calls into question the reported advantages of laparoscopic splenectomy, a procedure that even in expert hands involves longer operative time, greater blood loss, morbidity and transfusional requirements, particularly disadvantageous in children.

Laparoscopic treatment of spleen simple cycts

V. Koubishkin, V. Tsvirkun, D. Ionkin and V. Vukolov
A. Vishnevsky Institute of Surgery, 27 B. Serpukhovskaya st., Moscow, 113811 Russia

The task of our investigation was optimization of laparoscopic technique and evaluation of the results of laparoscopic operations in patients with symptomatic nonparasitic spleen cysts (SNPSC).

We have an experience of 24 organ preserving operations in benign lesions of spleen, five of them were performed laparoscopically. All five patients (four female and one male, aged 2±4·7 years) had long history of left upper abdominal pain. On US and CT the sizes of the cysts ranged from 5 to 12 cm. Serological tests excluded parasitic nature of the cysts. The patients have normal coagulogram and immunological status.

Laparoscopic intervention includes steps listed below: 1) Pneumoperitoneum. 2) Introduction of three trocars. 3) Puncture of the cyst and emergence cytology of content. 4) Excision of cyst's roof with its morphological investigation. 5) Hemostases and deepitelization of residual epithelial surface of cysts using 96° ethanol. 6) Washing out and drainage of operation field.

In some cases (residual cavity) we recommend to use glue and tamponade with greater omentum. The volume of operative bleeding was minimal.

Postoperative course in all patients was uneventful, on US there were no retention of fluid was found. All patients discharged in three days.

Long term results were excellent, the patients after organ preserving laparoscopic operation had no changes in immune system and hemostases in comparison with healthy control group.

Conclusion: Laparoscopic operation in SNPSC is a safe and effective procedure.

The treatment of splenic injuries: our experience

E. Montalvá, A. Vázquez, E. Artigues and R. Trullenque
Service of General and Digestive Surgery, Valencia University General Hospital, Valencia, Spain

Aim: The spleen is the most commonly affected organ in closed abdominal injuries. The management of splenic trauma has evolved towards more conservative options, as a result of diagnostic advances in the evaluation of the lesion, and resuscitation ward improvements.

Material and methods: A review was made of the clinical histories of 80 patients emergency hospitalized for splenic trauma between January 1991 and December 1997. The diagnostic procedures employed, management, the duration of hospital stay, and surgical morbidity-mortality were evaluated. A distinction was made between conservative medical treatment (non-operated patients), conservative surgery (with preservation of the spleen) and total splenectomy.

Results: Mean patient age was 32 years: 77·5 per cent were males and 22·5 per cent females. Traffic accidents were the cause in most cases (70 per cent), followed by pedestrian traffic injuries (16·2 per cent), accidental blunt trauma (7·5 per cent) and falls from a height (6·2 per cent). Echography was performed in 85 per cent, and CT in 67·5 per cent. Seven patients (8·7 per cent) underwent peritoneal punction-lavage, with hemoperitoneum in all of them. There were associated injuries in 52·5 per cent of cases. An emergency laparotomy was performed in three cases, without prior explorations, in view of the major hemodynamic instability observed. The splenic injuries were predominantly of type I (25 cases), followed by types II, III and IV (22, 17 and 16 cases, respectively). An expectant, non-surgical approach was adopted in 28 cases, while surgery was performed in the remaining 52 cases. Conservative splenic surgery was carried out in nine of these patients. Mean hospital stay was 10·5 days (10·5 and 12·4 days in the case of conservative surgery and total splenectomy, respectively), vs 14·2 days among those not operated upon. Admission to intensive care proved necessary in 37·5 per cent, with a mean stay of six days. Complications were in turn more frequent among the splenectomized patients – global mortality being 8·1 per cent.

Conclusions: The indications for conservative management are maintained, though limited by the risks involved in blood transfusion. The decision to either attempt to save the damaged spleen or remove it depends upon a precise quantification of blood loss, with a careful evaluation of splenic parenchymal losses – requirements which can only be properly met by an exploratory laparotomy. In any case, we consider that a splenectomy should be performed in the event of blood losses in excess of 1000 ml, with coagulopathy, associated lesions, involvement of the splenic hilus, or extensive splenic parenchymal damage.

Percutaneous drainage of splenic abscesses

M. Yakut, A. Tan, N. Kaymakcioglu, A. Simsek, M. Tasar, T. Bavbek and M. Bülbül *Gülhane Military Medical Academy, General Surgery Department 06018 Etlik, Ankara, Turkey*

Pyogenic splenic abscesses are rare conditions that tend to occur in patients with predisposing factors. Splenectomy is the standard surgical treatment for these lesions. Currently, with the improvements in imaging techniques, percutaneous drainage of splenic abscesses has been demonstrated to be one of the alternative treatments in selected cases. Computed Tomography (CT) or Ultrasound (US) guided percutaneous drainage decreases patient morbidity while decreasing the amount of patient trauma and preserves the splenic tissue with its immunologic role.

Seven patients with solitary splenic abscesses had percutaneous drainage in the last three years. Abscess cultures included salmonella species in six cases and mixed bacteria in one case. After the percutaneous drainage, one patient had intra-abdominal bleeding as a complication and underwent emergency splenectomy. Other six patients tolerated the procedures very well and CT showed small residual space on the 7th, 30th and 60th day after the percutaneous drainage.

As a result, although splenectomy remains the traditional treatment for bacterial splenic abscess, CT or US guided percutaneous drainage may be appropriate in carefully selected patients.

Carcinoma of the male breast. A retrospective study

M. Borrego Galán, A. Oltra, P. Yunta, C. Herrera, C. Sebastian, M. Meseguer, S. Sancho Fornos and C. Herranz *Servicio de Cirugía General I y Oncología Médica, Hospital Universitario 'La Fe', Av. Campanar 21, 46009 Valencia, Spain*

Introduction: Breast cancer represents less than one per cent of all malignancies in males. Because of its rarity this carcinoma has not been extensively studied.

Material and methods: We have retrospectively studied 27 men with breast cancer diagnosed and treated in our Institution from January 1969 to October 1997. The clinical features, diagnosis, treatment, histological findings and follow-up are analyzed.

Results: Mean age was 62 years. The presenting symptom was a mass in 67 per cent, nipple discharge 8 per cent, pain 7 per cent, nipple involvement 7 per cent, and others 11 per cent. None of the patients had gynecomastia. The most common site of the primary lesion was centrally located.

The median delay between the onset of symptoms and seeking medical advice was 27 weeks (range 2–480 weeks).

The staging of the tumours was: stage I: 3 patients, stage IIA: 6 patients, stage IIB: 4 patients, stage IIIB: 11 patients, stage IV: 2 patients.

Modified radical mastectomy was undertaken in 20 cases and simple mastectomy with axiliar dissection in 4 patients. Radiation therapy was carried out in 2 patients, hormonal therapy in 3, hormonal and radiation therapy in 6, hormonal and chemotherapy in two, chemo and radiotherapy in 1, radio and chemo and hormonal therapy in 8. Histopathology study showed: 22 invasive ductal carcinoma, 2 papillary carcinoma, 1 lobular carcinoma. Disease free interval was 42·5 weeks.

Conclusions: Our results indicate that male breast is an uncommon malignancy that is diagnosed 10 years later than in women and in a more advanced stage of disease. Skin involvement is more usual than in women. Gynecomastia does not seem to be associated with the development of breast cancer. Lobular carcinoma is possible in men.

Treatment algorithms we use in breast cancer in women seem to be fully indicated also in men.

Prognosis of these patients is the same in male and female patients when disease specific rate are compared. It is necessary for an early diagnosis and the institution of therapy at a stage when cure may be possible.

Breast tumour hypoploidy indicates fatal outcome

E. Chávez, J. Viñuela, J.L. Puente, J. Forteza, J Cameselle and J Potel *Surgery Department, Hospital General de Galicia, Santiago de Compostela, La Coruña – España*

Background: There is controversy as to the value of tumoral DNA index as a prognostic factor in breast cancer.

Aim: To investigate the individual prognostic values of different ploidy classes by determining the survival of patients of each class.

Methods: The DNA indices of 182 fresh-frozen tumour samples were determined, using normal mammary tissue as internal reference, in a Coulter Epics Profile II Flow Cytometer (samples were prepared by mechanical mincing in PBS and were labelled with propidium iodide). On the basis of their DNA indices, tumours were classified as hypoploid, diploid, near-diploid, hyperdiploid, tetraploid or polyploid. The patients were monitored at six-month intervals for up to five years.

Results: No patients with diploid, near-diploid or hyperdiploid tumours suffered relapse within the study period. Of the 62 with tetraploid tumours, five relapsed, four of whom died. Of the 22 with polyploid tumours, nine relapsed, six of whom died. All the 11 with hypodiploid tumours died. The 11 hypoploid tumours were all invasive ductal carcinomas, and in all 11 the mean size of the cell nucleus was abnormally small, but these cases differed as regards other prognostic factors (tumour size, histological grade, patient age, lymph node involvement and p53, Cerb-B2 and estrogens and progesterone receptor status).

Conclusions: The prognostic value of tumour DNA index in breast cancer is enhanced when subclasses of aneuploidy are distinguished. In this study, the mortality rate was zero for diploid, near-diploid or hyperdiploid tumours, and 100 per cent for hypoploid tumours. Hypoploidy may probably be considered an independent prognostic factor.

Advantages in free flap breast reconstruction – the deep inferior epigastric perforator flap

K. Exner and A. Peek *St. Markus-Hospital, Clinic of Plastic and Reconstructive Surgery D-60431 Frankfurt am Main, Wilhelm-Epstein-Straße 2*

Breast reconstructions with autologous tissue have been established worldwide. Lower abdominal skin and fat provides abundant source of tissue for the patient desiring breast reconstruction without a silicone implant. Loss of muscular stability and a 25 per cent rate of problems with microcirculation are disadvantages of the conventional pedicled TRAM flap. Free tissue transfer with microvascular anastomosis using the inferior epigastric vessels has much better blood supply than predicted TRAM, but there is still an 11 per cent rate of partial loss and fat necrosis. Since ALLAN developed the free DIEP flap for breast reconstruction functional and cosmetic donor defect has been minimized. This new method of breast reconstruction seems to have all the recognized advantages of the free TRAM flap without sharing its inherent disadvantages.

Our experience of this technique consists of its use in the reconstruction of 32 breasts, two patients with bilateral reconstruction. Mean age of the patients was 41 years. Revision of the arterial or venous anastomosis within three days after flap transfer was necessary in two patients due to thrombosis. Due to a postoperative haematoma around the pedicle arterial and venous interposition with vascular grafts were performed in one patient. Only in this case a 10 per cent loss of skin surface occurred. In 33 DIEP-flaps a perfect vascularisation of fat and skin tissue was achieved. Since the whole abdominal musculature were left intact, functional and aesthetic result of the donor side was even better than in free TRAM flaps using muscle sparing techniques.

Flap evaluation requires meticulous dissection of the perforators through the muscle to the parent vessels. Long vascular pedicles allow either the thoracodorsal or internal mammary vessels to be used as recipient vessels. Sensitive nerve coaptation is possible since segmental cutaneous nerves run with the perforators.

The authors demonstrate the operative details of this method and will discuss their experiences along with the advantages and disadvantages for breast reconstruction with autologous tissue.

Is axillary clearance merited in all women with breast cancer?

D.B. Kingsmore*, A. Ssemwogerere**, D. Hole**, C.R. Gillis** and W.D. George* **University Department of Surgery, Western Infirmary, Dumbarton Road, Glasgow, Scotland. **West of Scotland Cancer Surveillance Unit*

Aim: The necessity of axillary surgery is increasingly under question as the indication for chemotherapy broadens and the number of small, node negative tumours increases due to the screening programme. The purpose of this study was to assess the adequacy of axillary surgery in breast cancer by age and to investigate whether this consequently influences survival outcome.

Methods: All 7144 cases of histologically confirmed invasive breast cancers diagnosed from 1980–1994 in a defined geographical area were identified. From the original pathology reports was obtained tumour size, number of nodes removed and number positive. Mean follow up was 10 years. Inadequate axillary surgery was defined as removal of less than four lymph nodes.

Results: Inadequate axillary surgery was performed in significantly more women aged 65–74 years compared to younger women. The risk of death from inadequate surgery was significantly higher in women younger than 55. In contrast, older women with inadequate axillary surgery were not compromised in terms of survival.

Age	No. Nodes	5 Yr srvl	10 Yr srvl	R.H.R.	Sig.
<55	4+	73%	59%	1·00	baseline
	1–3	66%	51%	1·46	P<0·01
55–74	4+	72%	57%	1·00	baseline
	1–3	72%	57%	1·13	n.s.

Conclusions: We conclude that older women have received differential treatment of the axilla, but in this series, survival from breast cancer has not been adversely effected. Routine axillary clearance is thus not merited.

Immediate reconstruction in breast cancer surgery. 300 consecutive cases using prostheses and flaps

M. Montanari and O. Sidoli *Department of Senology – Fidenza General Hospital, Via G. Borghesi, I 43036 Fidenza (PR) – Italy*

Immediate breast reconstruction after cancer surgery gives the best results from the point of view of life quality. Reconstruction is necessary not only after total mastectomy but also in several cases of partial resection, i.e. central and inferior quadrantectomy.

In our department 300 consecutive cases of breast reconstruction were performed from 01/07/1992 to 30/09/1997 (91 mastectomies; 209 quadrantectomies). After partial resection we used mammaplasty like techniques sometimes associated with contralateral breast reshaping. Recently we noted better results using selective latissimus flap after central-inferior quadrantectomy (6 cases).

After mastectomy, 59 prostheses (usually permanent expander) in submuscolar pocket without other procedures and 32 muscolocutaneous flaps (25 latissimus, 7 TRAM flaps) were carried out.

Complications were: 1 expander infection during chemotherapy which required removal of implant and delayed TRAM flap; 2 liposclerosis of zone 3 in TRAM flap; 1 light cyanosis in latissimus flap resolved by hyperbaric treatment; 1 partial necrosis in superior pedicle reduction mammaplasty like technique; 1 month later debridement, wound nearing and areola by full thickness thigh graft were performed. No complication life threatening or significantly prolonging hospitalization was observed.

Length of operations and incidence of unsatisfactory aesthetic results are progressively decreasing.

On the basis of our experience and the data of other groups immediate reconstruction seems destined to be the treatment of choice in breast surgery, also for less technical problems.

Multidisciplinar oncological approach and informed consent are mandatory.

Clinical significance of collagenase-3 expression in male breast cancer

C. Serra[1], M.L. Lamelas[2], J.C. Rodriguez[2], L.O. González[2], A. Martinez[2], A. Baltasar[1], F. Vizoso[2] and C. López-Otín[3]
[1]*Servicio de Cirugía General, Hospital 'Virgen de los Lirios', Alcoy, 03804, Alicante, Spain,* [2]*Servicios de Cirugía, Ginecología y Anatomía Patológica, Hospital de Jove, Gijón, Asturias, Spain,* [3]*Departmento de Biología Funcional, Universidad de Oviedo, Spain*

Introduction: Collagenase-3 is a metalloproteinase that is known to be expressed by female breast carcinomas (Ogilvie et al., J Natl Cancer Inst 1985; 74: 19–27), and has a proteolytic role against some extracellular matrix components. Thus, its expression by tumours may facilitate tumoral invasion and metastasis.

Material and methods: In order to examine the potential value of collagenase-3 in male breast cancer (MBC) we have studied its expression in a group of 54 tumours from patients with MBC. Immunohistochemical assays were performed on tissue sections using the avidin-biotin method and the supersensitive system (Biogenex, San Ramon CA, USA). Curves of relapse-free-survival (RFS) and overall survival (OS) were established by the Kaplan-Meier method and compared with the log-rank test. Multivariate Cox's regression model was used to examine interactions of different prognostic factors. The mean follow-up period was 45·5 months.

Results: A total of 34 carcinomas (63%) stained positively for Collagenase-3. On the one hand: univariate analysis showed no significant association between collagenase-3 staining and tumoral size, axillary node status, histologic grade, or oestrogen receptor (OR)-status. On the other hand, multivariate Cox's regression model showed that Collagenase-3 expression was an independent prognostic factor of overall survival (P=0·01). Thus, patients with tumours that stained positively for Collagenase-3 had a higher relative risk (RR=2·19) of death than those that presented no staining (RR=0·26).

Conclusion: These results indicate that a high percentage of male breast tumours are able to express collagenase-3. In addition, this expression is associated with a more aggressive biological behaviour of male breast tumours.

Excision of perianal thrombosis and thrombosed external haemorrhoids under local anaesthesia

J.H.P.M. Jongen, J.-U. Bock, M. Reh and N.-P. Nuernberg
Proctological Office and Department of Proctology, Park-Klinik, Goethestrasse 11, 24116 Kiel, Germany

Because publications about the treatment of perianal thrombosis are rare, we reviewed all patients with a thrombosed perianal varix or a prolapsed thrombosed haemorrhoid, that were excised under local anaesthesia in the years 1995 and 1996. 136 patients (average age 41 years (17–81 years), 67 males, 69 females, 14 women during pregnancy) were operated on under local anaesthesia because of a thrombosed perianal varix (99) or thrombosed prolapsed haemorrhoid (37). Five patients were operated on 2–3 days before by other physicians because of the same disorder. All patients were treated as outpatients. The wounds after excision were left to heal by secondary intention. All patients were instructed to take sitz-baths and dressings with an astringent ointment.

Postoperative complications: four patients developed a fistulous tract on the bottom of the wound and needed additional surgery, one patient had a bleeding complication, that could be treated by local measures. Seven patients developed a recurrence. In the autumn months of 1996 (for the patients operated in 1995) and 1997 (for the patients operated in 1996) a standard questionnaire regarding recurrent symptoms, long-term complications and patient's satisfaction was sent to all patients.

The results of the follow-up by questionnaire show, that the excision of perianal thrombosis under local anaesthesia is justifiable and tolerable (most patients would have the operation done again under local anaesthesia, if necessary) and has few complications.

Comparison between bilateral gluteus maximus transposition and levator plasty in the treatment of faecal incontinence

B. Lestar, L. Ritter and J. Kiss *Imre Haynal Health Sciences University, Department of Surgery, Budapest, Szabolcs u. 33. H-1135, Hungary*

Aim of the study: Several operative techniques have been designed for the treatment of anal incontinence. When severe incontinence has to be cured while the anal sphincter is greatly damaged and unsuitable for repair, the anal sphincter muscle has to be substituted to get sufficient results. The outcome of the two types of operative technique has been compared, i.e. when the gluteus or the levator muscle was used for substitution.

Materials and methods: During the period from 1993 to 1997, bilateral gluteus maximus transposition was performed on eight patients (four males and four females, mean age: 38 years). The lower third of the gluteus muscle was mobilized medially from the sacrum on both sides. One of the resulting flaps was split longitudinally to create a triangle with the contralateral flap around the anal canal (Devesa method). Temporary diverting stoma was created in all patients before gluteus transposition. The other type of reconstructive surgery, levator plasty was performed in 31 female patients (mean age: 55 years). Levator plasty involves creating an 'artificial sphincter' by approximation of the pubococcygeus muscle between the vagina and the anorectum – following transperineal dissection of recto-vaginal septum. This manoeuvre enhances activation of the lateral muscle fibres of the levator plate, which are usually less damaged than the external anal sphincter.

Summary of results: Following gluteus transposition, the functional rehabilitation of transposed muscle was achieved by sphincter training for additional two to three months. The stomas were closed four to six months after reconstructive surgery. Continence improved in seven out of eight cases both according to the subjective opinion of patients and the manometrical results. Mean basal pressure increased from 20 to 30 mmHg; mean squeeze pressure rose significantly, from 40 to 90 mmHg. Levator plasty improved continence in 24 out of 31 patients. By manometry, mean basal pressure increased from 30 to 45 mmHg, whereas mean squeeze pressure improved from 55 to 75 mmHg.

Conclusion: In properly selected cases – when anorectal sensation and faecal consistence are normal – the functions of the external sphincter can be substituted by gluteus transposition. Temporary diverting stoma and postoperative sphincter training are prerequisites to acceptable functional results. Levator plasty can achieve acceptable functional result as well. This procedure is less aggressive than gluteus transposition, but when the pelvic floor is severely damaged (e.g. denervated), it is unsuitable for the restoration of faecal continence.

Third degree of hemorrhoidal disease – ligature or operation

B. Zagoričnik, L. Despotović and G. Seničar *Private Surgical Hospital 'Parks', Pap Pavla 33, 21000 Novi Sad, Yugoslavia*

Routine treatment of first and second degree of hemorrhoidal disease (HD) is conservative. For fourth degree treatment is commonly operative. Persisting dilemmas are about III degree: different authors are treating them with both methods, with various results. There are no clear indications about conservative or operative treatment for this degree. The aim of the study was to declare significance of pectinate line diversion as common factor determining the method of treatment.

All patients with grade III of HD (264) are divided in two groups: group A – patients with pectinate line in normal position inside anal canal (122); and group B – patients with partial or complete dislocation of pectinate line distally (142). Group A was treated with ligature by Baron, group B operatively, by Milligan-Morgan operation (122). Twenty patients from group B refused operative treatment. In group A we had good result in 91 patients (75 per cent), satisfactory in 18 (15 per cent), bad in 13 (10 per cent). In group B (operative treatment) good results in 97 (80 per cent), satisfactory 19 (16 per cent), bad 6 (4%). Patients in group B refusing operative treatment (20) were treated with ligature, but not with such good results as operative (good 0; satisfactory 11, bad 9).

Considering these results, authors are suggesting treatment of III grade of HD: when pectinate line is in place, treatment should be conservative, when dislocated pectinate line operative treatment should be applied. Also, from practical point of view, all grades of HD can be divided into two categories: 1. with pectinate line in place – conservative treatment (medicaments, IRC, ligature) and 2. with dislocated pectinate line – operative treatment.

Total mesorectal excision: results of two types of restorative proctectomy

E. Berg, A. Peters, P. Palma and J. Girona *Coloproctological Clinic, Prosper-Hospital, Mühlenstraße 27, D-45659 Recklinghausen, Germany*

Aim: To evaluate the perioperative complications and postoperative function following total mesorectal excision (TME) with restorative proctectomy for rectal cancer of the lower and middle third.
Materials and methods: From 5/96 to 1/97 of 156 patients with rectal cancer 42 underwent TME with (supra-)anal colonic **J**-pouch anastomosis. Perioperative data were collected retrospectively. A questionnaire, concerning functional outcome was undertaken six and 12 months postoperatively. Good results encouraged a prospective study to compare the colonic **J**-pouch of 5–7 cm length with a lateroterminal anastomosis with a 7 cm short limb (1.7.97–1.12.97). The first group comprised 19 patients, the second 16.
Results: In the first series we saw two deep vein thrombosis, one with a non-fatal embolism. Only five patients needed protective ileostomy. There were three radiological and two clinical anastomotic leakages. The latter necessitating covering stoma. All stomas were subsequently closed. No patient died. After six and 12 months the mean stool frequency was 4·3 (3–7) and 2·5 (1–4), respectively. The incontinence score of Jorge and Wexner (0–20) had a mean value of 2·4 (0–19). The second study with a total of 35 patients showed an anastomotic leakage rate of 16 per cent (3 of 19) for the **J**-pouch and 44 per cent (7 of 16) for the lateroterminal anastomosis.
Conclusion: Functional results of deep low anterior resection with restorative proctectomy are excellent. A short colonic **J**-pouch is superior to lateroterminal anastomosis because of fewer complications.

Resection and primary anastomosis with protective colostomy as an alternative to Hartmann procedure in left colonic peritonitis

S. Landen *Department of Surgery, St. Elisabeth Hospital, Brussels, Belgium*

Background: Hartmann's procedure remains the favoured option in patients with acute left colonic and sigmoid disease, despite the well documented morbidity associated with reversal. We performed a prospective study to determine whether primary anastomosis with protective colostomy constitutes a valid alternative to the Hartmann procedure.
Methods: Between July 1994 and July 1997 all patients with peritonitis due to free perforation of left colonic and sigmoid origin underwent resection and primary anastomosis with protective colostomy. Restoration of colonic continuity was programmed six weeks later, after verification of the anastomoses by gastrograffin enema. The group comprised five men and 13 women of mean age 73 years (32–97 years). Mean ASA and APACHE II scores were 2 and 12·5, respectively. The mean delay between onset of symptoms and surgery was 74 hours. Pathological examination showed diverticular disease in 17 patients and a ruptured leiomyosarcoma in 1 patient.
Results: Thirty-day mortality was 5.5 per cent (n=1) and hospital mortality was 11·1 per cent (n=2). No patients showed signs of suture disruption and routine radiological controls of all anastomoses at six weeks supported this. Mean length of hospital stay was 20±10 days. Closure of the colostomy using a small peristomal incision was performed in all surviving patients after a mean delay of 45±9 days. Mean length of hospital stay for colostomy closure was 7±3 days and this was accomplished without mortality. Outcome variables of the present group of patients were compared to those of a well-matched Hartmann control group. Mortality, morbidity and fistula rates were similar for the two groups. Duration of hospital stay and delay to stoma closure were shorter following primary anastomosis and protective colostomy ($P<0{\cdot}05$). Rates of stoma closure were higher in the primary anastomosis group ($P<0{\cdot}05$).
Conclusions: Primary anastomosis with protective colostomy is a valid alternative to the Hartmann procedure in left colonic peritonitis.

Pfannenstiel's incision in colorectal surgery

D. Lechaux, M.P. Lambert, B. Leroy, J.P. Lechaux and J.P. Lechaux *Hôpital des Diaconesses, 18 rue du Sergent bauchat, 75571 Paris Cedex 12*

A prospective study was undertaken between 1984 and 1987 to assess results of a transverse hypogastric laparotomy stemming from the Pfannenstiel incision in surgery of the left colon and rectum.

One hundred patients were operated on. The mean age was 61 years. Main operative procedures included: sigmoïdectomy (48), anterior resection of the rectum (24), rectopexy (12), abdomino-perineal resection of the rectum (5), total colectomy (5). Splenic flexure of the colon was mobilized in 23 patients. Four patients were operated on in one stage for colonic obstruction. Wound healing, post-operative pain and pulmonary disturbances have been evaluated.

There was no peri-operative death. Wound sepsis occurred in eight patients and hematoma in four patients. Seven patients had to be reoperated for complication by the same incision. Sixty one patients were available for follow up examination (median follow up: 75 months). There was no incisional hernia in spite of factors considered to increase the risk of parietal failure. Post operative ventilatory depression was evaluated by pulmonary function test, peak expiratory flow rate and blood gas analysis. Results were similar to those of a lower midline incision. Assessment of the post-operative pain score was made using a linear analogue scale. Requirement for analgesia was calculated. Pain was estimated moderate at 24 hours after surgery, low at 48 hours, absent at 72 hours. Analgesia was not required at 72 hours for 65 per cent of the patients.
Conclusion: The Pfannenstiel mini-laparotomy provides the greatest strength to the abdominal wall and minimizes the post operative pain and respiratory depression. It is suitable for colo-rectal surgery usually performed through a lower and upper midline incision or even a complete median laparotomy. With a combined strategy of early oral nutrition and mobilization, this incision achieves a minimally invasive, stress reducing, procedure.

Results of laparoscopic cholecystectomy

A. Bubnys, L. Noreika, D. Ribokas, G. Brimas, G. Simutis, J. Umbrasas and V. Lipnickas *Clinic of Abdominal Surgery, Vilnius University Santariskiu Hospital, Santariskiu 2, 2600 Vilnius, Lithuania*

Aim: To evaluate the results of laparoscopic cholecystectomy (LC) in the 5 years period.

Patients and methods: First LC in Lithuania was performed at our clinic in December 1992 and introduced for treatment of patients with symptomatic gallbladder disease. From December 1992 to December 1997 LC was performed in 2282 patients. Mean age 50·1 years (ranged from 14 to 88 years) among 1973 women and 309 men. 226 (5·5 per cent) of the cases were patients with acute cholecystitis.

Results: Conversion to open cholecystectomy (OC) was necessary in 77 patients (3·3 per cent). Operative complications occurred in 12 (0·5 per cent) patients: CBD lesions – in 10 (0·44 per cent) patients, bleeding from a. cystica – 2 (0·09 per cent) patients. In six patients CBD injuries were recognized at the time of operation and after conversion to OC primary ductal repair was performed. In case of bleeding from a. cystica conversion to OC and ligation were performed. Postoperative complications occurred in 64 (2·8 per cent) patients: a) local infection – in 39 (1·7 per cent) patients (subhepatic abscess – 10, phlegmona of the abdominal wall – 1, wound infection – 28), in three cases subhepatic abscess was successfully drained by ultrasound guided percutaneus approach; b) bile leakage – in 21 (0·9 per cent) patients; c) haemoperitoneum because of the bleeding: – from the abdominal wall at the trocar insertion site – in two patients; from a. cystica – one patient; d) obstructive jaundice due to stone in CBD – in 2 patients (endoscopic sphincterotomy and stone extraction was performed). There were 31 reoperations due to complications: 18 laparotomies and 13 relaparoscopies. Two patients (75 and 87 years old) died after LC – mortality 0·09 per cent.

Conclusions: To prevent iatrogenic CBD injuries correct preparation with a clear identification of the anatomic structures is essential. Relaparoscopy and ultrasound guided percutaneus drainage can be successfully used in the treatment of complications after LC.

Transinguinal diagnostic laparoscopy to evaluate presence of contralateral hernia in children

R. Clavería, X. Feliu, P. Besora, E. Fernández-Sallent, J. Camps, E. Macarulla, J.M. Abad, H. Basas and H. Hassan *Department of Surgery, Hospital General d'Igualada, P. Verdaguer 128, 08700 Igualada, Barcelona, Spain*

Introduction: The incidence of indirect inguinal hernia in infants is about five per cent but the presence of contralateral patent processus vaginalis (PPV) is as high as 80 per cent and only 10 per cent of the patients evolve into a hernia.

The highest incidence of PPV is found in the first months and decrease until two years old.

Advances in laparoscopic instrumentation have permitted new applications in abdominal surgery.

Transinguinal diagnostic laparoscopy can be used to identify the presence of an indirect hernia.

Materials and methods: We described the technique that we used to contralateral inguinal exploration during the inguinal herniorraphy.

A 5 mm Port is placed into the hernia sac and fixed with a vessel loop.5–6 mm Hg pressure in Trendelembourg position. 30° laparoscope is inserted through the port and the contralateral side is evaluated. Takes no more than 3 minutes of surgery time.

Only if the evaluation is positive a contralateral repair is performed.

Results: Since 1996 we have used this procedure in all the children where we suspected a contralateral hernia with good results.

Conclusions: 1) Laparoscopic evaluation of the contralateral side via the open hernia sac is quick, safe and effective; 2) The operating time is low;
3) Transinguinal diagnostic laparoscopy may benefit the children with a suspected contralateral hernia and permit to repair during the same operation.

Laparoscopic cardiomyotomy with anterior fundoplication for esophageal achalasia and postoperative manometric assessment

Z. Hajdu[1], S. Kathy[1], I. Kósa[2] and Gy.G. Kiss[2] *Department of Surgery*[1] *and 2nd Department of Internal Medicine*[2], *Kenézy Teaching Hospital of Med. Univ. School, Debrecen, Hungary*

Aim: The laparoscopic cardiomyotomy with anterior fundoplication (Heller–Dor procedure) is accepted for treatment of esophageal achalasia. The aim of our study was to evaluate the effect of Heller's cardiomyotomy with Dor fundoplication on the basis of our experiences and postoperative manometric investigations.

Methods: Between December 1994 and December 1997, 19 patients with esophageal achalasia underwent laparoscopic Heller's operation with Dor's antireflux procedures. In three patients endoscopic dilatation was tried previously. Preoperative assessment involved clinical, radiological, endoscopic and manometric investigations. In all patients postoperative clinical examinations and routine manometry were performed six months later.

Results: Operation time was 35–90' (mean 55'). All patients were free from dysphagia and regurgitation during the follow-up period. Conversion to laparotomy was not required. There was one esophagus perforation requiring reoperation. Postoperative manometry in all the patients showed a decreased lower esophageal sphincter pressure (mean 12·8 Hgmm). Three of 19 patients had a normal esophageal peristalsis and 16 of 19 had hypomotility six months later.

Conclusion: Based on the obtained results which compare well with those of the literature, it could be concluded that cardiomyotomy with Dor fundoplication through a laparoscopic approach leads to good functional results and seems effective in treating esophageal achalasia.

Endoscopic resection of epiphrenic esophageal diverticula

T. Horbach, T. Reck, C. Schneider, F. Köckerling and W. Hohenberger *Department of Surgery, University Hospitals, Krankenhausstr, 23, D-91054 Eerlangen, Germany*

Epiphrenic diverticula of the esophagus are rare findings in comparison to pharyngoesophageal diverticula. The epiphrenic diverticula are mostly seen in younger patients and are accompanied with symptoms like regurgitation, mediastinal and pleural inflammation or abscesses and esophageal motility disorders.

The established surgical treatment of epiphrenic diverticula is anterolateral thoracotomy and open resection. This method goes along with severe morbidity for the patient (pulmonal complications, intercostal neuralgia, prolonged total parenteral nutrition, etc.).

A combined endoluminal and endocavital endoscopic operation to our opinion seems to be a more recent minimally invasive technique. During this procedure we localize the diverticulum intraoperatively with a flexible endoscope which also works as an esophageal splint and allows continuous endoluminal control of the margins of resection. A thoracoscopic access is used to facilitate the dissection of the diverticulum using a harmonic scalpel and to resect the diverticulum with an endostapler.

A naso-gastro-jejunal triple-lumen-tube positioned intraoperatively under endoscopic guidance allows continuous gastral decompression and early postoperative jejunal feeding. Total parenteral nutrition with all its complications and costs is made unnecessary.

Technical details of the procedure will be demonstrated as well as the perioperative management.

Laparascopic transabdominal preperitoneal (TAPP) or total extraperitoneal (TEP) inguinal hernia repair

Ö. Ibrahim, D. Sezai and A. Osman *Ankara Mevki Asker Hastanesi Genel Cerrahi Servisi Çankırı Cad., Dışkapı-Ankara 06100 Türkiye*

Aim of study: If we operate on inguinal hernia with a laparoscopic procedure, we have got two approaches for its repair. First is Trans Abdominal Preperitoneal approach (TAPP) and second is Total Extraperitoneal (TEP) one. We think that some objective criterias must be used to decide which approach is suitable.
Patients and methods: 120 patients treated by laparoscopic inguinal hernia repair between November 1994 and March 1997. Last 100 cases were included in this study. Patients mean age was 30 (16–77), all were male. Hernias classified according to Nyhus classification. TAPP carried out in 76 patients and TEP in 22 patients. Conversion to open procedure for two patients ocluded due to adhesion relating to previous abdominal operation. There was bilateral hernias in 19 of 100 patients, 11 of them were known preoperatively and eight of them were recognized in the course of TAPP laparoscopic hernia repair (14·8 per cent). Polypropylene mesh was used to reinforce for abdominal wall defect, and fixed by stapler.
Summary of results: Some minor complications such as scrotal echymosis, haematomas resolved spontaneously. Scrotal seromas were aspirated percutenously. Two port entrance wound infection were improved by dressings. Complications as ileus, subileus, and fistula were not seen. After bilateral TEP repair, Meralgia Paresthetica was seen on left thigh and improved three months later.
Conclusions: We need to choose an approach according to hernia type and patient's anatomy. We prefer the TAPP way to TAP for four conditions. First, peritoneal dissection and closure in unilateral scrotal type IIIb, IIIc, and IV are easier than TEP. Second, operative in TAPP way especially view in small and short patients is larger than TEP. Third, TAPP is useable for patients who had been operated on in hypogastric quadrant of abdomen. Fourth, if there is another disease which may be treated with laparoscopic approach we will do that with TAPP approach. When patient has got ingüinal hernia type II unilateral (maybe scrotal), type IIIa and IIIb nonscrotal and bilateral inguinal hernia we prefer TEP to TAPP. The operating time is shorter than TAPP and there is no need to enter peritoneal cavity.

We think that these criterias have to be determined exactly and could be standardized with a number of studies of laparoscopic approach techniques.

The endoscopic preperitoneal inguinal hernia repair (TEP)

J.M. Ramon, X. Carulla, A. Serrano, J. Roura, J. Castillo, J. Solsona and J.M. Sánchez Ortega *Hospital Universitari del mar de Barcelona, Pg. Marítim. 25–29, 08003 Barcelona*

Aim of the study: The endoscopic preperitoneal hernia-plasty (TEP), described in 1993 by McKernan, combine the herniaplasty preperitoneal of Nyhus results with the advantages of the less invasive surgery, avoiding with that the risks of the transperitoneal laparoscopic access (TAPP).

We analyse our experience with the TEP technique in the treatment of inguino-crurals hernias.
Materials and methods: From November 1995 to December 1997, performed a total of 81 hernioplasties in 60 patients, 18 (30 per cent) of them by recidiva and 21 (35 per cent) bilaterals. The technique consisted in the placing of a 12 × 8 cm PROLENE mesh closing the myopectineo hole at preperitoneal level, fixed by helicosuture and under regional anesthesia.
Summary of results: Those series included 55 (91·6 per cent) men and 5 (8·4 per cent) women, with an average age of 53·6 years (between 28 and 87). The operatory time was 37 minutes (20–90) for unilaterals and 63 minutes (40–90) for bilaterals. The only intraoperatory complication was the peritoneal puncture in 11 (13·5 per cent) patients, that forced to practise 7 (11 per cent) reconversions (5 by Nyhus and 2 by TAPP). Postoperatory complications were 5 (8 per cent) seromas and 1 (1·6 per cent) recurrent hernia. The hospital stay was of about 1·6 days (1–4).
Conclusions: The TEP technique is a safe process and with an acceptable technical complexity, that allows under regional anesthesia the repair of all types of hernias. The morbidity and recurrent hernia rates are comparable with conventional hernioplasty.

Anatomy of biliary ducts and blood supply as a risk factor of the laparoscopic cholecystectomy

S. Rudzki and M. Jesipowicz *First Department of General and Transplant Surgery of Medical University in Lublin, Poland, 8 Jaczewskiego Street*

Common biliary duct lying most superficially in hepato-duodenal ligament structure is easily accessible in surgery for cholelithiasis. It constitutes the basis of Calot's triangle – the area so individual that it can only be compared to a fingerprint. Laparoscopic cholecystectomy (l.ch.) in early period increased the number of biliary duct (b.d.) injury. The authors performed 50 resin casts of the liver extra- and intrahepatic b.d. and arteries in order to find the critical points in the anatomy and vascularization of extrahepatic b.d. As for the anatomy of b.d. there are two dangerous points: atypical bifurcation of hepatic ducts and long and very narrow common b.d. In the first point cystic duct situated close to vesicularis artery may be reason of its injury. In the second point overstretching of cystic duct may be the cause of c.b.d. injury, that is the most common reason for injury (three cases). We found that the origin of cystic artery and its running was externally atypical in two cases. Analysing blood supply of common hepatic and b.d. we found one case where its vascularization was extremely dependent on cystic artery. In four cases cystic duct was running close to common hepatic duct anastomosing with it very low. Dissecting cystic duct on a long part of its length can cause injury to blood supply of the lateral wall of common hepatic duct and result in necrosis with early bile leakage or late stricture. As well as using electrocautery in the region of hepato-duodenal ligament close to the common bile duct may often lead to the injury of the blood vessels of the duct which may result in the lack of blood supply and consequently in necrosis with leakage of bile or in inflammatory infiltration changes in the middle part of the duct which can result in mild jaundice. So in our examination, 20 per cent of cases showed extremely atypical anatomy creating possibilities for l.ch. complications.

Safety of laparoscopic cholecystectomy in patients with relative contraindications

Iv. Tzvetkov, V. Dimitrova, N. Hinkov, K. Ignatov and R. Gaidarski *Clinic General Surgery, University Hospital, 8 'G. Kochev' Street, Pleven – 5800, Bulgaria*

The safety of laparoscopic cholecystectomy in patients with relative contraindications (acute cholecystitis, gallstone pancreatitis and choledocholisthiasis) was evaluated in a four-year retrospective review. The study was organized as results of three groups were compared. First group was of 130 patients with relative contraindications for laparoscopic cholecystectomy (LC). The second group was of 240 LC in patients with conventional cholecystecomy and indications for operation were the same as for the first group. Operations done between January 1992 to September 1997 were included in the study. Patients were followed up three months to four years after operation. We found one lesion of common bile duct in first group – 0·76 per cent. No postoperative hernias or late complications were found. Conversion of LC in the second group was done in nine cases – 2·6 per cent. Intraoperative lesion of common bile duct was found in one case. The patient was reoperated five days after the first operation. We had no mortality or other serious complications in this group. No post-operative hernias or late complications were found. In the third group intraoperative lesions of common bile duct were registered in two cases – 0·75 per cent. Reoperations due to different reasons were done in five cases – 0·3 per cent. Postoperative complications and hernias six months after operation were found in four patients. Laparoscopic cholecystectomy in patients with relative contraindications was a safe procedure. Results showed that convertion rate, lesions of common bile duct or other late complications were not much more as in patients with no contraindications.

Symptomatic relief following laparoscopic Nissen fundoplication – does it last?

M.K. Lingam and G. Bell *Department of Surgery, Inverclyde Royal Infirmary, Greenock, Scotland*

Early experience suggested that laparoscopic fundoplication was effective. The need for longer term follow-up was apparent. Forty patients (mean age 55, range 25–74) underwent laparoscopic Nissen fundoplication by a single surgeon from January 1992 to June 1996. Mean operating time was 156 mins (range 40–270 mins) and mean hospital stay was 6.5 days (range 4–18). Mean length of follow-up was 25·2 months (range 4–54 months). Six procedures were converted to open and seven included concurrent laparoscopic cholecystectomy. Thirteen patients experienced some dysphagia during the post-operative period which was usually mild; seven of these 13 settled spontaneously and the others responded to single bougienage. 25 patients had an excellent sustained response being entirely symptom-free at latest review (mean 25·3 months, range 5–50 months). 11 had mild residual symptoms, the most prevalent of which was dysphagia. Four subsequently suffered reflux symptoms requiring medication at latest review. Two of these enjoyed symptomatic relief six and 14 months symptom-free prior to recurrence of their symptoms. This study shows that it is possible to achieve complete and lasting relief from reflux symptoms with laparoscopic Nissen fundoplication.

Prognostic value of the Dukes classification for adenocarcinoma of the stomach

P. Aurello, G. Ramacciato, F D'Angelo, C. Cicchini and A. Napolillo *First Department of Surgery, University of Rome 'La Sapienza', Viale del Policlinico, 155 00161 Rome, Italy*

The aim of this study is to explain whether the classifications according to Dukes and Astler-Coller are helpful also in the management of gastric carcinoma. During the period from 1983 to 1993, 438 consecutive patients affected by gastric cancer underwent curative surgical treatment at I Department of Surgery of the University of Rome 'La Sapienza'. Each tumour has been staged according to Dukes, Astler-Coller's, TNM-UICC (3rd Ed – 1987) classifications on the basis of histopathological features. The level of lymph node metastases has been evaluated according to the general rules for gastric cancer by the Japanese Research Society for Gastric Cancer. The five-year survival rate (s.r.) has been determined according to the Kaplan-Meier method. All observed data were analysed by means of the chi-square test. Results were considered statistically significant at $P<0\cdot05$. The follow-up has been carried out on 406 patients. For each class of the Dukes, Astler-Coller and TNM-UICC classifications cumulative five-year s.r. were determined and compared. The five-year s.r. was 96·4 per cent in the Dukes A, 84·5 per cent in stage B, and 32·5 per cent in stage C. In the Astler-Coller's system the five-year s.r. was: 100 per cent in A, 96 per cent in B1, 84·5 per cent in B2, 45·8 per cent in C1, and 27·7% in C2. In the TNM-UICC staging the five-year s.r. was: 96·8 per cent in IA, 91·5 per cent in IB, 68·9 per cent in II, 44·1 per cent in IIIA, 18·2 per cent in IIIB, and 3·2 per cent in IV. In the Dukes classifications system there was a significant step-wise relationship between tumour stage and survival: A vs B $P<0\cdot05$, B vs C $P<0\cdot0001$. On the contrary the Astler-Coller's system showed lower correlation between stage and survival: A vs B1 p.n.s., B1 vs B2 $P<0\cdot05$, B2 vs C1 $P<0\cdot001$; C1 vs C2 $P<0\cdot005$. We conclude that the Dukes classification is a simple and easy staging system with a prognostic value also for patients affected by gastric cancer.

Results of open and laparoscopic gastric banding in the treatment of severe obesity

F. Berrevoet, P. Pattyn, S Ulens, U.J. Hesse and B. de Hemptinne *Department of Surgery, University Hospital De Pintelaan 185, 9000 Ghent, Belgium*

The surgical treatment of morbid obesity has become routine clinical practice in many centers. Since 1991 several authors have been performing gastric banding with an adjustable band, because of both simplicity and effectiveness of the technique. A laparoscopic approach has obvious advantages in the treatment of these patients.

Patients and methods: From August 1995 till September 1997 80 patients were treated with surgical gastric banding. Preoperatively body mass index (BMI) was calculated and only BMI>35 was considered indication for operation. Initially a laparotomy was performed as part of the learning curve, but subsequently laparoscopy was intended in every patient. All patients had several dietary regimens without success. Postoperatively the frequency of adjustment of the band, weight loss, short- and long-term complications and number of reoperations were studied. Mean follow-up was 12 months (range 2-26 months).

Results: A total of 80 procedures were performed, 3 by laparotomy, 73 laparoscopic and 3 patients had a laparotomy after conversion. Mean BMI was 45 (range 36 to 57). All patients had at least one adjustment of the band (mean 1·3 times) with injection of some physiologic fluid or urografine. Vomiting occurred in all patients during the first few weeks. Complications of total dysphagia for both fluid and food was seen in 18 patients (21·6 per cent), in 8 cases a laparoscopic replacement of the banding was inevitable, while in two cases a laparotomy had to be performed with removal of the band. Conservative treatment with removing fluid from the band was possible in the other patients. Mean hospital stay was 3·3 days (range 2–6 days). Mean weight loss after 1, 6 and 12 months was 6 kg (range 0–11·5 kg), 22·3 kg (range 0–36 kg) and 27 kg (range 0–60 kg) respectively.

Conclusion: This preliminary study shows the feasibility and safety of laparoscopic gastric banding with minimal discomfort after surgery, short hospital stay and excellent short- and long-term results concerning weight loss.

Quality of life after gastrectomy for cancer: a quantitative analysis

L. Bruno and F. Montinaro *Istituto di Clinica Chirurgica Generale e D.C., Università di Firenze, Italy*

Aim: Surgery offers the only possibility of cure for gastric cancer (GC) patients. Since longer survivals have recently been achieved, more attention should be directed to the relief of symptoms and to the quality of life (QOL). In our study, patients were interviewed to assess whether the operative procedure was justified in terms of QOL.

Materials and methods: 73 patients operated on between 1986 and 1996 and without recurrence of disease after a minimum follow-up period of six months were studied by using a survey examining food tolerance, body weight and performance status (PS). Scores were assigned by the questioner for each response to express quantitatively the degree of physical and social well-being. The lower the score, the higher the discriminant power to indicate a good QOL. Average scores were calculated and statistical analysis was carried out to clarify whether some clinicopathological parameters may influence answers.

Results: Most patients were consuming a normal diet after operation but 57·5 per cent (42/73) were unable to tolerate the same volume of food. Eight out of 22 patients (36·4 per cent) had lost over 5 kg within 2 years of surgery and this incidence was 7/16 (43·8 per cent) more than 5 years after operation. A lower PS was present in 7/22 (31·8 per cent) and 1/16 (6·3 per cent) cases, respectively. Differences between answers did not result statistically significant according to the above mentioned variables and noticeably concerning the type of surgery.

Conclusions: The outcome after surgery is commonly based on morbidity and mortality, but little information is available regarding the QOL which is a very important endpoint in patients assessment. Our findings suggest that most patients surviving radical surgery for GC enjoy a good QOL in absence of recurrence.

Prognostic factors in node-negative gastric cancer

L. Bruno and F. Montinaro *Istituto di Clinica Chirurgica Generale e D.C., Università di Firenze, Italy*

Aim: The presence of lymph node (LN) metastasis closely correlates with survival of gastric cancer (GC) patients. Although prognostic value of the number and level of invaded LN has been discussed, clinicopathologic features and prognostic indicators of node negative (N–) GC patients have not yet been studied.

Material and methods: Between 1986 and 1996, 311/387 GC patients underwent surgery at our Institute (resectability rate. 80·4 per cent). After excluding 18 stump cancers, 105 out of 293 (35·8 per cent) were identified with histologically negative LN by hematoxylin-eosin staining and form the basis of our study. Patients were stratified according to several clinico-demographic and pathologic variables. Data are expressed as mean (s.d.). Kaplan-Meier survival curves were successively compared according to log-rank test. A uni- and multivariate analysis was then performed by using Cox model.

Results: Age of our patients was 66·6 (10·9) years. The number of dissected LN was 15·3 (9·2). The distribution according to depth of invasion was T1 55, T2 28, T3 22. Five-year survival rate for the whole series was 73 per cent, with a median survival of about 50 months. Serosal invasion (p 0·001), residual disease (p 0·028), non-intestinal type (p 0·031) and standard (<25 removed LN) lymphadenectomy (p 0·049) were all independent predictors of survival.

Conclusions: Our data confirm the good outcome of N-GC patients. The prognostic value of serosal invasion, residual disease and histologic type has already been discussed. Although it is initially counter-intuitive that these patients should benefit from a D2 dissection, our findings seem to point out the value of such a lymphadenectomy in that group of patients.

Surgery of gastric lymphoma

J. Kocik, H. Nottberg, J. Brockmann and N. Senninger
Department of Surgery, University of Münster/Germany, Waldeyerstraße 1, 48149 Münster, Germany

Introduction: Despite a large number of publications within the last few years it is undoubted that many questions concerning Non-Hodgkin-Lymphoma of the gastrointestinal tract still have to be answered.

We present some preliminary results of a prospective multicenter trial from Germany.

Patients and methods: Up to January 1997 data from 403 patients suffering from the disease were collected from 154 hospitals. Treatment included operation on one hand, radiation (depending on stage and grading IF 30 Gy and 10 Gy Boost or 40 Gy abdominal bath) and/or chemotherapy (CHOP or MCO) on the other hand.

Results: 99 patients with gastric lymphoma were operated (ratio m:f=1·5:1, mean age 54·5 years [19–81 years]). Though all patients underwent preoperative upper gastrointestinal endoscopy the diagnosis was known in only 61/99 patients at the time of operation. The most frequent operative procedure was partial or total gastric resection with or without lymphnode dissection. According to the Musshoff classification 38 patients (38 per cent) were classified stage IE, 36 patients stage IIIE (36 per cent), 13 patients stage II2E (12 per cent), 6 patients stage IIIE (7 per cent) and stage IVE (7 per cent). In only 46 per cent (46 patients) a curative R0-resection could be achieved. Up to now there is no significant difference in survival between the operated patients and those who were treated by CTX or RTX (logrank test, $P=0{\cdot}64$).

Conclusion: We conclude that at the moment there is no gold standard in the therapy of gastric Non-Hodgkin-Lymphoma.

Vertical banded gastroplasty at more than five years

E. Marcote, A. Baltasar, R. Martínez, F. Arlandis, R. Bou, C. Serra, M. Bengochea and J. Miró *'Virgen de los Lirios' Hospital. The Surgical Service Alcoy, Alicante, Spain*

Introduction: Some bariatric surgery techniques were hopeful in the short term follow up, but failed in the long term due to undesirable side effects or by insufficient weight loss. This paper shows our experience with VBG (vertical banded gastroplasty) in our first 100 consecutive patients after follow up of more than five years.

Materials and methods: Sixty patients were MO (morbidly obese) with BMI (body mass index) (kg/m^2) between 40–50 and 40 patients were SO (superobese) with BMI over 50. Initial weight was 12·565 kg (range 85–223), ideal weight 58·37 kg (range 47–83), excess weight 69·28 kg (range 38–161) and BMI 47·86 (range 37·87).

The original Mason VBG was performed in nine patients. The operation was changed to a V.L.S. (vertical line separation) because of the high rate of S.L.D. (staple-line-discruptions). This modification consisting in the complete division of the vertical line using linear staplers and a serosal patch. The TA 90 BN stapler, that simplified the operation, was used in ten patients. All pouches volumes were inferior to 20 ml. One patient died two days after re-stapling due to pulmonary embolism. Surgery was required in 25 patients, 25 per cent, due to failure of the technique (SLD, dilatation of the pouch, leaks).

Results: Change in per cent EWL (percentage of excess weight loss) is probably the easier and best measure of weight loss. The per cent EWL was 54·3 per cent and BMI 33 at five years. Individual results for our MO patients are 27 good and 29 failures, and for SO patients 13 good and 23 failures. None of the patients who got surgical benefit were able to eat a regular diet. Eleven patients (27·5 per cent) were having diets unable to eat bread or meat, 11 (27·5 per cent) diets excluding rice and fish, 7 (17·5 per cent) diets type puree and 11 (27·5 per cent) diets based on sweets. Foot intake and quality of life were affected in most patients due to the restrictive condition of the operation. We also asked patients about their satisfaction with the technique, and of those who answered, 54 were happy (67·5 per cent), 11 patients were undecided (13·75 per cent), and 15 patients (18·75 per cent) considered that the operation was negative and would not recommend it to anyone.

Discussion: The VBG operation is: 1) safe; 2) reproducible and with an easy learning curve but; 3) easily reversible by removing the band; 4) few patients had long term complications due to the technique, and 5) the stomach is easily studied by x-ray or endoscopy.

In our experience, VBG has some disadvantages: 1) *High reoperation* rate, mainly due to SLD; 2) *Quality of life* is affected, since patients are unable to eat regular food; 3) *Weight loss is inadequate*. The maximum per cent EWL occurs at two years but this loss is not generally maintained, as many patients become 'sweet eaters' and 'shake drinkers'.

Conclusions: VBG is a simple and safe technique with low mortality and minimal long term complications. The drawbacks are the high reoperation and conversion rates, poor weight loss, regaining weight and poor quality of life due to the restrictive condition of the band that can be enhanced by the use of complex operations.

The role of extended radical surgery in gastric cancer

G. Osmanoğlu, A. Bulut, D. Seker, Z. Ergül, İ. Baran, and O. Kaya *SSK Ankara Hospital, 3rd Clinic of General Surgery, Dıskapı, Ankara, Turkey*

We define extended radical surgery in gastric cancer as: total gastrectomy + complete lymph node dissection + local peritoneal implant excision + splenectomy and distal pancreatectomy. According to some authors, radical lymph node dissection added to total gastrectomy increases the survival rates.

In between the years 1991–1997, radical extended surgery had been performed to 100 patients (61 male, 39 female) in our clinic. Ages of patients differ in between 38–73 (median age, 52). R-2 lymph adenectomy had been done in 90 cases and R-3 lymph adenectomy had been done to rest of patients. The average number of lymph node excised per operation was 40. For reconstruction, we had done 33 omega, 40 Roux-en-Y and 27 Tanner-19 eosophagojejunostomy. The median hospital stay period of patients was 10 days.

The follow up period of patients differs in between one month and six years. Since this clinical research is still continuing we can not interpretate the five-year survival rates and compare our results with the survival rates of classical total gastrectomy. But our results seem that extended radical surgery gives patient more survival chance.

Surgery of peptic ulcer in changing times

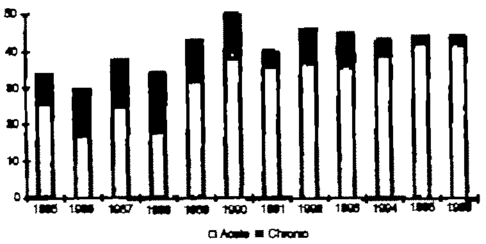
C. Tónus, P. Appel, E. Weisenfeld and H. Nier *Städtische Kliniken Offenbach, Chirurgische Klinik I, Starkenburgring 66, 63069 Offenbach, Germany*

Object of the study: Influence of the introduction of Omeprazole on surgical treatment of peptic ulcers.

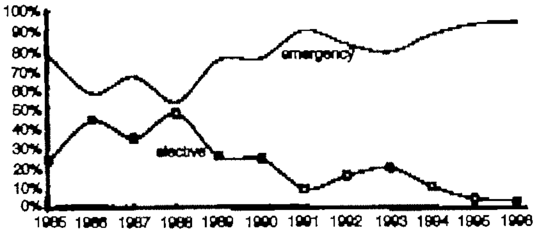
Material: Between 1985 and 1996 485 patients (291 male [60 per cent] and 194 female [40 per cent]) (mean age 59 years) underwent a gastrosurgical treatment because of peptic ulcer. 29·3 per cent of the patients had gastric ulcers (n=142), 70·7 per cent had duodenal ulcers (n=343). In all 79·2 per cent of our operations (n=384) were performed under emergency conditions (56 per cent with perforation, 20 per cent with penetration, 24 per cent with bleeding ulcer); only 20·8 per cent were performed regular (n=101) 71·8 per cent of the collective had concurrent diseases (n=348).

Results: Between 1985 and 1996 the quantity of operations because of peptic ulcers was constant (figure 1) But differentiated – in relation to

1



2



the years – the number of emergency cases increased and the number of electice indications decreased (figure 2) The favourite method of operation changed – because of the option of conservative treatment – from resective type to local excision The total complication rate was 48 4 per cent (n=235), the lethality rate 21 2 per cent (n=103) Correlations could be proved between age of the patient, comorbidity, condition under which the operation was performed (emergency or elective), hamoglobin <8 0 g/dl, size of the ulcer on the one hand and morbidity and lethality on the other

Conclusions: The introduction of Omeprazole changed the nature of operative indications for complicated ulcers Consequence was an increased number of emergency cases with rise in morbidity and lethality

Nutritional status, dietary habits, eating related symptoms and quality of life after total gastrectomy and Roux-en-Y-reconstruction

J Vaqué, S. Sancho Fornos, J. Del Pino, J.L. Ponce, C. Sebastián, S. Carceller, P. Yunta and M Meseguer *Department of Surgery, University Hospital La Fe, Valencia, Spain*

Total gastrectomy (TG) is believed to be followed by serious nutritional consequences This study was organized to analyse the influence of this type of operation on several nutrition variables and eating-related symptoms

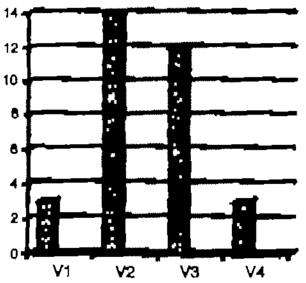
Thirty-three disease-free patients were evaluated a mean of five years after total gastrectomy for cancer The study encompassed nutritional assessment by standard anthropometric and biochemical indices, evaluation of the nutritional intake based on 24 hour recall, anamnestic analysis of postcibal symptoms and syndromes and quality of life according to the Visik and Troidl grading.

Body weight had declined progressively until the 12th postoperative month Had dropped more significantly weight loss in actual body weight/usual body weight compared with actual body weight/desirable body weight Measured tricipital skinfold, arm muscle circumference and arm muscle area had dropped not significantly less in patients undergoing TG

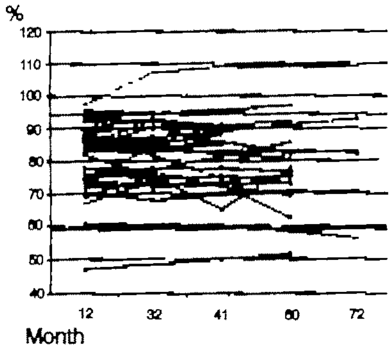
The principal symptom has been the diarrhoea (62 5 per cent), that improvement significantly to the end of 12 months (32 7 per cent) The episodes of pain or dumping were scarce

The little group of patients reported both reduced feelings of hunger and appetite Similar conclusions were observed when patients were assessed for quality of life (see figure below)

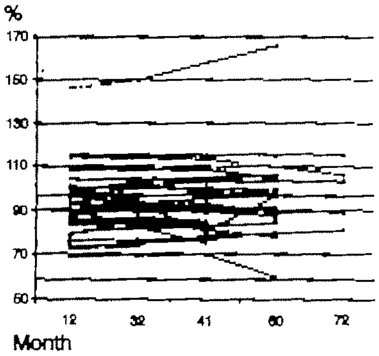
These data suggest that malnutrition after TG is relatively mild and that this operation causes only a limited impairment of the nutritional state, and spares most of the nutritional variables of clinical interest. These findings argue in favour of TG when clinically indicated without excessive concern about postoperative nutrition



Visik grading



Actual/usual body weight



Actual/desirable body weight

Laparoscopic ultrasonography reliably visualizes bile duct injuries – results of a blind randomized animal study

M. Birth, F. Bruckmans, U. Janzen and H.-F. Weiser *First Department of General, Viszeral- and Thoracic Surgery, Diakonie-Hospital, 27342 Rotenburg/Wümme, Germany*

Aim of the study: Only one third or less of bile duct injuries that occur during Laparoscopic Cholecystectomy are detected at the primary operation in spite of using intraoperative cholangiography. There is a need for investigation other intraoperative diagnostic methods for their possibility of detecting bile duct injuries like laparoscopic ultrasound. Detection of different bile duct injuries by laparoscopic intraoperative ultrasonography was evaluated in a blind randomized animal study.
Materials and methods: Fifty bile duct injuries were created using laparoscopic techniques in 23 farmer pigs. The number of the single lesions and the order in which the injuries were created was randomly assigned. The lesions created were: 1) Partial occlusion by a clip; 2) Complete occlusion by a clip; 3) Partial laceration; 4) Transection without clips; 5) Transection between clips; 6) Excision between clips. There were also cases without lesions. Different types of clips were used. By laparoscopic ultrasound using a flexible probe a screening of the injuries was attempted. The study was performed in a blind fashion.
Summary of results: Complete imaging of the hepatic and common bile duct from its bifurcation to the insertion in the duodenum was accomplished in all 23 animals before surgery was done. All eight cases where no lesion was performed were recognized correctly. In 48 of 49 cases the injury was diagnosed (sensitivity: 98 per cent). One injury was obvious without ultrasound. There were 44 exact diagnoses and 12 cases where injuries were recognized but could not be differentiated exactly (specificity of 100 per cent overall accuracy of 98·3 per cent). There was only one false diagnosis. The different type of clips could also be differentiated.
Conclusions: Laparoscopic ultrasonography can reliably visualize most relevant bile duct injuries. A standard for doing the ultrasound examination is proposed. Direct and indirect ultrasound signs of bile duct injuries are explained.

Supurative cholangitis in malignant biliary tract obstruction

T. Coskun, N.A. Kama, Y.N. Yuksek, G. Daglar, M. Ozkirki, A.Z. Akat and E. Kesici *Ankara Numune Hospital, 4th Department of Surgery, Türkiye*

Aim: Cholangitis is a serious and potentially lethal disease particularly in the patients with malignant biliary tract obstruction, requiring prompt recognition and treatment. Our purpose in this study was to present the common characteristics and outcome of the patients with supurative cholangitis and to find out the factors that were closely associated with development of this serious disease in malignant biliary tract obstruction.
Patients and method: Between 1992–1997, 62 patients were operated on for malignant obstruction of the biliary tract. Of these patients 16 were found to have supurative cholangitis at laparotomy. Of the patients with cholangitis, 9 were males and 7 were females with a mean age of 62 (range 42–85 years). The cause of malignant obstruction was gallbladder carcinoma in 2 cases, cholangiocarcinoma in 5 cases, and periampullary carcinoma in 9 cases. Of these 16 patients, only one had prior operative manipulation of the biliary tree (local resection for an ampullary tumour six months ago). Twenty-three parameters were analysed to find out the risk factors that were associated with development of supurative cholangitis: a) clinical – age, sex, weight loss, fever, localization of carcinoma, b) laboratory – hematocrit, white blood count, platelet count, blood urea nitrogen, creatinine, albumin, bilirubin, SGOT, SGPT, alkaline phosphatase; c) preoperative – hospitalization time, oral intake, nasogastric decompression, positive blood cultures, blood transfusion, total parenteral nutrition, ERCP and antibiotic treatment. The chi-square analysis was employed for correlation of individual risk factors with cholangitis. Stepwise logistic regression analysis was then used to identify independent risk factors.
Results: Of the patients with supurative cholangitis, 7 (43·8 per cent) had Charcot's triad of symptoms and 1 had Reynold's pentad. Four patients (25 per cent) found to have hepatic abscesses at laparotomy. Six of 16 patients survived postoperatively and were discharged from hospital, while 9 patients died during the first hospital admission. Death was due to biliary sepsis in 5, anastomotic leakage in 2, acute renal failure in 1, and intra-abdominal hemorrhage and sepsis in 1 patient. In univariate analyses, white blood count (P=0·001), fever (P<0·01), ERCP (P<0·01), bilirubin level (P<0·01), preoperative positive blood culture (P<0·01), and preoperative hospitalization time (P<0·05) were found to have a significant correlation with the development of cholangitis. Multivariate analysis revealed that only bilirubin level, fever and ERCP were independently associated with supurative cholangitis.
Conclusion: The results of this study have shown that fever, high serum bilirubin level and ERCP performed in the preoperative period were independently associated with supurative cholangitis in malignant obstruction of the biliary tree. Since the development of cholangitis was highly lethal in malignant obstruction, identification of these risk factors may be worthwhile in the early diagnosis and treatment of the disease, and in prolongation of life.

Iatrogenic bile duct injuries – aetiology, surgical approach, prognosis

S. Kılıcturgay, H. Bilgel and Y. Özen *Uludağ University Medical School, Department of Surgery, 16059 Bursa, Turkey*

Aim: The aim of this study was to analyse the factors affecting the success of the surgical correction of iatrogenic bile duct injuries (IBDI).
Materials and methods: During a nine year period (1988–1997) 36 patients with iatrogenic bile duct injuries were reoperated in our center. 25 of them were female and the median age was 41·7 years. At admission 3 patients had biliary fistula, 2 patients were septic and had secondary biliary cirrhosis and the rest had obstructive jaundice with cholangitis. The surgical procedures causing IBDI were cholecystectomy (17 elective, 7 emergency, 5 laparoscopic) in 29 (80·5 per cent), subtotal gastric resection in 3 (8·4 per cent), hydatid cystectomy in 3 (8·4 per cent) and repair of blunt liver injury in one (2·7 per cent) patient. IBDI were corrected by primary common bile duct repair in 5, choledochocholedochostomy in 1, choledochoduodenostomy in 9, choledochojejunostomy in 5, hepaticojejunostomy in 17 patients.
Results: 5 patients (14·7 per cent) had biliary stricture within 4–36 months 4 of whom were reoperated (hepaticojejunostomy) and one underwent balloon dilation. Two of these hepaticojejunostomy patients had recurrent biliary stricture and needed balloon dilation. The mortality and morbidity rates in this series were 8·3 per cent (3 patients) and 30·5 per cent (11 patients), respectively. The two most important factors affecting mortality and morbidity were the delay in referral and the degree of liver injury.
Conclusion: IBDI have a high mortality and morbidity rates. Therefore these patients must be referred early to a center experienced in hepatobiliary surgery.

Mirizzi Syndrome – type II

A. Kitanovic, R. Djordjevic, M. Miladinovic, M. Smiijkovic, V. Kulic, M. Gajic and D. Stankovic *Health Centre Krusevac, Department of Surgery, Krusevac, Yugoslavia*

This work presents our experience in surgical treatment of obstructive icterus which is caused by the calculus compression from the gallbladder on the hepaticohcoledochus or by prolapse of calculus through the biliobiliaris fistula.

In the period between 1992–1997, 16 patients have been operated, and a type II of Mirizzi syndrome was found present. A compression was found in 10 patients, and a bilio-biliaris fistula in 6. Analysing the clinical picture, the anamnestics data have been examined, the diagnostic procedures, the surgical procedure and postoperative complications.

In all patients, a moderate bilirubinemia has been found, of an intermittent type. By the ultrasound examination a huge calculosis has been found. The icterus without bilio-biliaris fistula, were solved by cholecystectomy, 7 cases by partial, and 3 cases by complete cholecystectomy. With bilio-billiaris fistula 3 were solved by Roux-en-Y hepaticojejunostomy, and 3 by a suture of existing defect with a T tube According to sex, there were 13 women and 3 men, according to age most of them were in their VII decade The average length of hospitalization was 10 days From the postoperative complications we had 3 wound infections

In operations for obstructive icterus it is necessary to take into consideration before and intraoperatively the possibility of an existence of Mirizzi syndrome and especially when it is impossible to separate hepatoduodenal ligament from the gallbladder. Cholecystomy and extraction of calculus make the operation easier and contribute to easier solution of the problem with decrease in intraoperative complications.

Intrahepatic sclerosing cholangitis

E. Montalvá, A. Vázquez, E. Artigues, F. Peiró, A. Alberola,
M.J Garcia-Coret, R. Fabra and R. Trullenque *Service of General and Digestive Surgery, Valencia University General Hospital, Valencia, Spain*

Aim of the study: Sclerosing cholangitis (SC) is diagnosed by cholangiography and histology, as the clinical manifestations and laboratory parameters are nonspecific We report a case of SC of the left intrahepatic duct, and comment on the preoperative diagnosis and surgical management

Clinical case: A 69-year-old male was admitted with occasional right hypochondrial colic pain. The clinical, laboratory and radiological studies were unrevealing Abdominal CT and echography showed hepatomegaly, with dilatation of the left intrahepatic biliary tract containing echogenic images. The right intra- and extrahepatic biliary tract showed no dilatation or pathology The gallbladder was free of stones. Transparietohepatic puncture of the left intrahepatic biliary tract yielded thick bile; the bacteriological and cytological studies were negative. A decrease in caliber of the left intraheptic biliary tract was noted on day 3, with the presence of stenosis of non-tumoral appearance. MR cholangiography showed a slightly rosary-like image that was very apparent in the left intrahepatic biliary tract region. With the diagnosis of stenosis of the left intrahepatic biliary duct and intrahepatic lithiasis, surgery was performed The left liver lobe was slightly indurated, the macroscopic appearance being otherwise normal Intraoperative cholangiography showed a normal biliary tree without contrast passage into the left intrahepatic duct A left liver lobectomy and cholecystectomy were performed. The surgical piece presented a dilatation of the left intrahepatic biliary tract, which contained stones and presented periductal fibrosis. The histological diagnosis was SC

Conclusions: SC involves inflammation, fibrosis and gradual destruction of the intra- and extrahepatic biliary ducts, the latter are affected in 87 per cent of cases, while in 11 per cent and 2 per cent only the intra- and extrahepatic ducts are respectively involved The rare presentation of our case (SC limited to a small portion of the intrahepatic bile duct) led to the differential diagnosis between primary intrahepatic lithiasis and repeat cholangitis and SC

Surgical management of symptomatic biliary lithiasis during the third trimester of pregnancy

Th. Montariol, N. Bataille, P. Sebe, G. Candelier, P. Julienne and F. Chleq *Centre Hospitalier 78105 Saint Germain en Laye, France*

In the past two years 1996 and 1997, 240 patients with biliary lithiasis were operated in the department of surgery and 4375 pregnant women came to delivery in the department of obstetrics. During this time, we had to operate six patients with complicated biliary lithiasis during the third trimester of pregnancy.

They were 17 to 34 years old (mean age 24·8), between 26 and 33 weeks of gestation, had non resolutive biliary colic and ultrasonographic gallstones Two of them had acute pancreatitis with an enlarged common bile duct (CBD) and increased serum amylase Open cholecystectomy was performed without cholangiography in all patients Two had preoperative endoscopic sonography confirming a free CBD Choledocotomy with extraction of CBD stones and T-tube drainage was performed in the two patients with pancreatitis All six patients recovered without surgical complication. One went in preterm labour 12 hours after operation and five went to term. All delivered healthy infants

According to the literature, complicated biliary lithiasis is not uncommon during pregnancy and biliary pancreatitis is associated with a high rate of maternal mortality and/or fetal loss Recent reports of open or laparoscopic cholecystectomy have demonstrated a favourable outcome during the second trimester When biliary lithiasis becomes symptomatic during the third trimester, our experience leads us, for the same reasons, to propose early open cholecystectomy to avoid complications of CBD stones

Early cholecystectomy is a safe procedure in patients with symptomatic biliary lithiasis during the third trimester of pregnancy

Recurrence rate of common bile duct stones is higher after endoscopic sphincterotomy than after common bile duct exploration in patients below 60 years of age: a longterm follow-up stay

A.G Peppelenbosch, A.H.J. Naber* and H. van Goor
Department of Surgery and Gastro-Enterology, University Hospital Nijmegen, The Netherlands*

There is a tendency to treat patients with common bile duct stones younger than 60 years by endoscopic sphincterotomy and stone removal instead of surgical common bile duct exploration Longterm complications, in particular stone recurrence, after sphincterotomy in these patients are unknown. We studied retrospectively all patients below the age of 60 years who underwent endoscopic sphincterotomy (ES) or common bile duct exploration (CE) between 1978 and 1988 for common bile duct stones, focusing on early and late complications In this period 132 patients were treated, 55 by CE and 77 by ES. Follow-up was complete in 83 per cent of patients Mean (s.d.) follow-up was 11 (4) years in both groups of patients. Both groups were comparable in age, sex ratio and preoperative morbidity Two patients (4 per cent) died after CE, zero (0 per cent) after ES. Early complications occurred in 22 per cent and 18 per cent after CE and ES, respectively (P=n.s.). Duct clearance, as visualized by cholangiography, was achieved in 93 per cent after CE and in only 66 per cent after ES. In patients without duct clearance, spontaneous flow-down of stones was expected Longterm evaluation revealed 2 per cent of patients with cholangitis and 2 per cent of patients with common bile duct stenosis after ES, whereas this percentage was 0 per cent in the CE group Three years after operation, one of the 44 (2 per cent) patients in the CE group had recurrent stones, in contrast to 12 of 63 (19 per cent) patients after ES ($P<0·05$) Stones recurred on average five years after ES and were all removed by (re)sphincterotomy Stone recurrence was not due to incomplete duct clearance at the initial procedure.

It is concluded that treatment of common bile duct stones by endoscopic sphincterotomy in patients below 60 years of age, is associated with a higher incidence of stone recurrence in comparison with treatment by surgical common bile duct exploration

Surgical treatment of benign biliary obstructive jaundices

P. Poves, M. Borrego, P. Yunta, J. Del Pino, C. Herrera,
J. Silvestre, C. Sebastian and S. Sancho-Fornos *Servicio de Cirugia General I. Hospital Universitario 'La Fe', Av. Campanar 21, 460009 Valencia, Spain*

In patients with symptomatic benign biliary obstructive jaundices, the management has been controversial since the introduction of endoscopic retrograde cholangiopancreatography

Aim: The aim of this study was to evaluate the treatment of choice that include however other surgical options.
Material and methods: We analysed in a retrospective study the actiology and the surgical techniques of 266 patients with benign biliar obstruction. Between 1989 and 1996 we had treated 210 cases of secondary choledocholistiasis (78·94 per cent), 16 cases of residual choledocholistiasis (6·1 per cent), 2 cases of primary choledocholistiasis (0·74 per cent), 13 cases postoperative strictures (4·88 per cent), 11 cases of chronic papilitis (4·13 per cent), 3 cases of hydatic cyst (1·12 per cent) and 7 cases of chronic pancreatitis (2·63 per cent).
Results: One hundred and fifty underwent T-Kehr drainage (56·39 per cent). We have performed 77 biliary anastomosis: 60 choledochoduodenostomies (22·5 per cent) and 17 hepaticojejunostomies (6·39 per cent). We had operated 13 sphincterectomies by duodenostomy (4·88 per cent) and 26 were performed by endoscopic retrograde cholangiopancreatography (ERCP).
Conclusions: Our experience indicates that laparotomy could have been avoided in many cases if ERCP could have been performed sooner. It may be in selected patients the initial surgical option for decompression in the cases of benign biliary obstructive jaundices, that make possible the placement of successful endoscopic endoprothesis in the biliary duct. However bilio-enteric bypass with a Roux-en-**Y** jejunal loop yields a superior postoperative quality of life. We believe there exists a great variety of techniques performed in the management and treatment of the benign obstructive jaundice. Thus, we have to choose the optimal surgical technique.

Surgical management of iatrogenic bile duct injuries

R. Vecchio, F. Palazzo, F. Di Franco, S. Parisi, M. Di Martino and F. Latteri *Department of Surgery, University of Catania, Italy*

Iatrogenic bile duct injuries (BDI) are the most challenging complications following gallbladder surgery. Treatment options include surgery and, recently, interventional endoscopy and radiology. The results of the latter procedures still need to be compared with the surgical ones. We have reviewed 36 patients with BDI surgically treated from 1973 to 1997. Indications and results of reconstructive surgery have been evaluated according to the time of recognition and type of lesion, which have been reclassified. 30 patients had their initial surgical repair in our institution, whereas 6 patients were referred to us after a previous attempt of repair performed elsewhere. In the latter cases a choledocoduodenostomy (4 patients), an end-to-end biliary-biliary anastomosis (1 patient) and a hepaticojejunostomy (1 patient) were the initial surgical procedures. Hepaticojejunostomy was our procedure of choice (performed in 28 cases as first attempt and in 1 case after the failure of an end-to-end repair), followed by choledotoduodenostomy. 40 operations have been performed on 36 patients. Mortality and morbidity rates were 0 and 8·3 per cent, respectively. In a median follow-up of 3·5 years, 1 biliary fistula and 2 post repair bile strictures were recorded. One patient who first underwent an hepaticojejunostomy needed two reoperations consisting of surgical dilation of anastomosis and a subsequent cholangiojejunostomy (Longmire procedure). One patient who was initially treated with T-tube placement, was operated later on with a choledocoduodenostomy for biliary stricture. Another patient after an initial end-to-end repair required an hepaticojejunostomy for biliary fistula. Because of its good results in long-term follow-up, surgery still remains the treatment of choice in most types of BDI.

Thoracoscopic management of giant bullous emphysema

T. De Giacomo, F. Venuta, E.A. Rendina, E. Guarino, A.M. Ciccone, P. Iannitelli, M. Moretti, M.T. Aratari and G.F. Coloni *University of Rome 'La Sapienza', Department of Thoracic Surgery, Policlinico 'Umberto I' Viale Policlinico 00161, Rome, Italy*

Indications for thoracoscopic treatment of bullous emphysema are identical to those for open procedures, but because video-assisted thoracoscopy (VAT) is less invasive, it can be offered to patients in poor general condition, previously considered at excessive risk for thoracotomy. Resection of compressive, space occupying, non-functional bullae, allows the re-expansion of the compressed more functional lung, improving ventilation, gas exchange with reduction of ventilation/perfusion mismatch. We describe our experience in the thoracoscopic approach to severe bullous emphysema. During the last five years, 24 patients with severe bullous emphysema (23 M and 1 F) with a mean age of 57 years (range 32 to 76 years) underwent thoracoscopic bullectomy. Mean preoperative Forced Expiratory Volume in 1 second (FEV_1) was 32 per cent ranging from 14 to 65 per cent. VAT was performed with 3 to 4 access ports. Single lung ventilation was achieved with a double lumen endotracheal tube. After complete mobilization of the lung, the bullae were resected using 35 or 45 mm endoscopic staplers. Bovine pericardial strips were used to buttress the staple lines when needed. Parietal pleurectomy was generally performed while in 3 cases, a thoracoscopic pleural tent was created to prevent an apical pleural space. Two chest tubes were usually left in place. All patients were extubated at the end of the procedure or shortly thereafter. No perioperative mortality occurred. Prolonged air-leak >7 days was the most frequent complication seen in 9 patients (37·5 per cent). Two patients had cardiac arrhythmias and 1 patient presented with self limiting bleeding requiring transfusion. Mean duration of chest drainage was 9 days (range 4 to 20 days). Mean post-operative hospital stay was 13 days ranging from 5 to 25 days. Improvements in FEV_1, although modest, reached statistical significance as did decreases in residual volumes (RV). Clinical improvement was evident in all patients. Six patients were receiving oxygen before operation. Four of these were able to discontinue oxygen therapy completely and the remaining 2 were able to reduce their oxygen need. In conclusion, thoracoscopic approach to severe bullous emphysema is safe and effective. This less invasive approach, an alternative to thoracotomy, can be offered also to compromized patients with satisfactory results and acceptable rate of complications.

Value of rethymectomy in myasthenia gravis

E. Espin, J.M. Ponseti, J.L. Sanchez, C. Vicens and M. Armengol *Myasthenia Gravis Unit, Department of Surgery, Hospital General Universitario Vall d'Hebron, Universidad Autonoma de Barcelona, Spain.*

Myasthenia gravis is a neuromuscular autoimmune disease, in which the thymus gland is thought to play a central role in the pathogenesis. Thymectomy is now the standard therapy. Surgical-anatomic studies indicate that thymic tissue is widely distributed in the neck and anterior mediastinum, with microscopic foci of ectopic thymus in pericapsular mediastinal fat. Persistence of symptoms in patients who have undergone previous conventional thymectomy has been attributed to microscopic thymic remnants.

Material and methods: Between 1967 and 1995 we have performed 355 thymectomies in myasthenic patients, 98 of them with thymoma. The results after surgery are: 176 remissions, 108 therapeutical-remissions, 33 patients remain unchanged, 11 are worse. There have not been perioperative mortality, but 27 patients eventually died during the entire follow-up period. Reoperations for myasthenia without thymona were done in seven patients who had incapacitating weakness after conventional trans-sternal operations. All of them were females, younger than 30 years old (II-b Osserman class) with histopathological findings of hyperplasia of the thymus, under treatment with high dose of immunosuppressive therapy (prednisone, azathioprine, cyclosporine and courses of high-dose immunoglobulin or plasmapheresis) and more than five years from the previous operation. After preoperative preparation with high dose of IGIV, a repeated thymectomy was done by median sternotomy with removal of all the mediastinal fat. Mediastinal pleura was incised bilaterally from the level of the thoracic inlet to the diaphragm and again to the phrenic nerves, anterior pericardiophrenic fat, the fatty tissue in the region of the aortopulmonary window deep under the innominate vein, pretracheal fat and the superior poles of the thymus between the thymus and the thyroid isthmus. We separated the specimen in seven blocks. All the specimens were removed and submitted to the pathologist in marked separate containers for microscopical study. Chest tubes were placed bilaterally.

Results: The microscopical studies demonstrated that six of the seven patients had multiple foci of ectopic thymus. There was no perioperative mortality but we found higher morbidity, increased operative time, and more blood loss than first elective thymectomies. Three patients needed blood transfusion. The overall regression of the symptoms and signs of myasthenia in all of our patients was high, with less incidence of crisis and decreases of dose of medical treatment needed, but none achieved a total remission after three years of repeated thymectomy.

Conclusions: Rethymectomy in myasthenic patients with poor results after initial operation, found ectopic thymic foci in the surrounding adipose mediastinal tissue in almost all patients. Reoperation in these patients improved the results but none achieved a total remission. Our data support re-thymectomy in only selected cases.

Clinical appearance, imaging approach and operative treatment of pulmonary sequestration in adults

S. Eggeling[1], J. Böttger[1], K. Uschinsky[2], C. Engelmann[2] and K. Gellert[1] [1]*Department of Surgery, KH Lichtenberg, Fanninger Str. 32, 10365 Berlin;* [2]*Department of Thoracic Surgery, FLT, Karower Str. 11, 13125 Berlin*

Pulmonary sequestration (P.S.) is a rare congenital anomaly of lung parenchyma (0·15–5 per cent of anomalies of the respiratory tract) that consists of a partial or complete separation of lung parenchyma without appropriate bronchial and vascular connections. Most of these malformations are detected and treated in infancy because of recurrent pulmonary infections or solitary masses on chest X-ray. In adults, clinical appearance is more variable. Recurrent pneumonia (30 per cent), a hemoptysis (15 per cent), chest pain or pleural effusion are the most common symptoms, nevertheless about 40 per cent of adults with P.S. are asymptomatic.

Between January 1964 and January 1997 we operated 29 patients with P.S. (14 males and 15 females, age range 18–69 years, mean age 39·6 years). We saw lower lobe (89·6 per cent) and left sided (62 per cent) predominancy, intralobar type of P.S. occurred in 65·5 per cent, extralobar type in 31 per cent, mixed type in 3·4 per cent (1 patient). A wide variety of imaging techniques were used in the diagnosis of P.S. We performed chest X-ray in all, CT-scan in 48 per cent, aortography in 27·5 per cent and MRI in 10·3 per cent of our patients. In our retrospective series only 9 cases (31 per cent) were correctly diagnosed before operation. All other patients were operated upon because of persisting cystic or bronchiectatic findings or under suspicion of malignancy.

In all cases we found an anomalous systemic artery feeding the P.S., most frequently arising from the abdominal or thoracic aorta. We also found arterial supply originating from the subclavian artery, from an aneurysm of an intercostal artery or a double supply from the internal thoracic artery. Operation consisted of resection of the pathological specimen and ligature of the feeding systemic artery. We performed lobectomy in 26, pneumonectomy in two and typical resection of left segment 8–10 in one patient. Postoperative course was uncomplicated in 96·5 per cent. After discharge from hospital all symptomatic patients were without any complaint.

P.S. is a very rare, but important disease. Next to complications like recurrent infections or haemaptysis an accidental neglect of the anomalous systemic artery can be responsible for severe intra- or postoperative bleedings. We therefore recommend considering the possibility of P.S. in cystic or tumour-like changes of the lower lobes.

Surgical treatment of myasthenia gravis: our experience based on 67 cases

J. Furák, I. Troján and T. Szőke *Albert Szent-Györgyi Medical University Department of Surgery, Szeged, Hungary P.O. Box 464, H-6701*

This paper reports the results of surgery and care of 67 patients treated for myasthenia gravis (MG).

Patients: Between 1980 and 1996, 67 patients were operated on because of MG. The average age was 32·4±4·6 (19–67) years. As concerns the sex distribution we had 50 women and 17 men. The average period between the first symptoms and surgery was 2·2±0·6 (0·2–6) years. The severity of the disease was classified on the Osserman scale: stage I: 9 patients (13·4 per cent); stage II/A: 35 patients (52·2 per cent); stage II/B: 19 patients (28·4 per cent); stage III: 4 patients (5·9 per cent).

Treatment: The indications for surgical treatment of MG were Osserman stage I (if the symptoms did not reduce in response to medication), II/A, II/B and III, and thymoma. In all cases, the thymus and the perithymic fat tissue were removed via a median sternotomy. Histological processing indicated no thymoma in 51 patients (76·1 per cent), and thymona in 16 patients (23·9 per cent). In 4 of the 51 MG patients without thymoma (5·9 per cent), histology revealed ectopic thymus tissue in the perithymic fat. Preoperative plasmapheresis was performed in 5 of the patients in Osserman stages II/B or III, and in one case (III/A) during the postoperative period.

Results: There were no perioperative deaths. 45 patients (67·2 per cent) could be extubated in the operating theatre, and 20 patients (29·8 per cent) within 10 hours. In 2 cases (in stage II/B), the tracheal tube could be removed within 48 hours. Control examinations were carried out after 3 months, 6 months, 1 year and 5 years. After 3 months, the remission rate was 14·6 per cent, the palliation rate was 58·2 per cent; and after 5 years these were 31 per cent and 86 per cent.

Conclusions: In the surgical treatment of MG, we consider it justified to carry out thymectomy via a median sternotomy, and removal of the perithymic fat tissue. The reason is, as our findings demonstrate, that the perithymic fat tissue may contain ectopic thymus tissue, which – if left – can cause MG symptom recurrence after surgery. Median sternotomy appears most suitable for this.

Early results of pulmonary thromboendarterectomy

H. Oelert and E. Mayer *Department of Cardiothoracic and Vascular Surgery, Johannes Gutenberg-University Hospital, Langenbeckstr. 1, 55101 Mainz, Germany*

Objective: Pulmonary thromboendarterectomy is a potentially curative procedure in chronic thromboembolic pulmonary hypertension. Between June 1989 and December 1994, 109 consecutive patients underwent thromboendarterectomy at our institution. Multiple changes in the surgical concept and postoperative management have been implemented since January 1995. We report the early results of 45 thromboendarterectomy operations performed between January 1995 and September 1997.

Methods: Forty-five patients (19 females, 26 males; mean age 56 years, range 29 to 72 years) were operated using cardiopulmonary bypass, deep hypothermia and circulatory arrest periods. Preoperative NYHA functional class was III in 28 and IV in 17 patients. Preoperative pulmonary vascular resistance (PVR) and mean pulmonary artery pressure (mPAP) were elevated to 1023±230 dynes 's' cm^{-5} and 50±13 mmHg respectively.

Results: The mean circulatory arrest time was 37 minutes (range 8 to 72 minutes). The median duration of postoperative mechanical ventilation was 38 hours (range 10 to 390 hours). The in-hospital mortality rate was 8·8 per cent (4 of 45). In 41 survivors, PVR and mPAP were significantly reduced to 319±143 dynes 's' cm^{-5} (P<0·001) and 26±11 mmHg (P<0·01) respectively. Two-dimensional echocardiography (n=25) revealed a significant improvement of right ventricular fractional shortening from 20±12 per cent preoperatively to 31±16 per cent postoperatively (P<0·05).

Conclusions: In patients with severe chronic thromboembolic pulmonary hypertension, good haemodynamic and symptomatic improvements can be achieved by pulmonary thromboendarterectomy. Based on a learning curve and by changes of the perioperative management, the operative risk can be improved to an acceptable level.

Indications, results and complications of video-assisted thoracoscopic surgery

S. Suba, T. Laisaar, A. Ilves and T. Vooder *Department of Thoracic Surgery, Tartu University Lung Hospital, Riia str. 167, EE2400 Tartu, Estonia*

Aim of the study: Analyse our experience in video-assisted thoracic surgery.

Materials and methods: From January 1996 to December 1997, 173 patients (106 males and 67 females with mean age of 49 years) underwent VATS procedures with non-specific (24), tuberculous (19) or malignant pleural effusion (26), disseminated lung diseases (21), encapsulated pleural empyema (11) and clotted haemothorax (5), pneumothorax (13), peripheral lung nodules (25), pleural tumours (5), lung tumours (6), mediastinal tumours (6), lung abscess (3), sympathectomy (4), achalasia (1), foreign body (1). In 3 cases the final diagnoses were not found out.

Thoracotomy was necessary ten times for technical reasons and seven times for oncological reasons. Thoracotomy in the postoperative period was carried out in 4 cases because of persistent air leakage and 1 case developed an abscess in the thoracic wall. 1 patient died during the operation.

Conclusions: The advantages of video-assisted thoracoscopic surgery for patients include minimal operating trauma, reduced if pain, earlier postoperative mobilization, for some indications a shorter hospitalization period and required VATS could be performed using local anaesthesia.

Tracheo-bronchial resections for upper airway stenoses and tumours

Dr. I. Troján, Dr. T. Szőke, Dr. J. Furák *Albert Szent-Györgyi Medical University, Department of Surgery, H-6701 Szegend, P.O. Box 464, Hungary*

Between 1980 and 1994, 61 operations were performed because of lesions causing stenoses of the trachea, bifurcation and main-stem bronchi. The trachea was resected in 41 cases. Resection was necessitated by post-intubation or post-tracheotomy stenosis in 39 patients, and by a primary tumour of the trachea in 2 cases. Three out of the 31 upper tracheal stenoses were associated with a tracheo-oesophageal fistula. In 2 of these, closure of the fistula was combined with tracheal resection. In 4 cases, the bifurcation was resected because of the tumour. In 15 cases sleeve pulmonectomy was carried out, while in 13 and 2 cases, respectively, the right lung or the left lung was removed together with the bifurcation. In 1 case, a complete traumatic rupture of the right main-stem bronchus was recognized only in a late stage, and it was necessary to remove the upper lobe and to re-anastomose the intermediate bronchus to the bifurcation.

Four of the 61 patients died, a surgical mortality of 6·5 per cent. These patients had undergone resection for a benign tracheal stenosis in 1 case, resection of the bifurcation in 1 case, and sleeve pulmonectomy in 2 cases. In 2 of these 4 fatalities, the cause of death was a suturing insufficiency. The longest segment removed from the trachea was 5 cm. The anastomoses were sutured with 3–0 absorbable suture material with interrupted sutures. In 1 case, an early membrane-like stenosis was excised. In a further 2 cases, a 30 per cent stenosis developed in the line of the anastomosis, and this did not necessitate a re-resection.

The survival rate following resections for malignant tumours depended on the stage and the N status. T_3N_0 tumours had a 5-year survival rate of 28 per cent, while the T_3N_2 tumours survival rate was 10 per cent. With a view to preventing the occurrence of anastomotic stenoses in the postoperative period, the patients underwent routine bronchoscopy both 2 and 6 weeks following the operation.

Thymectomy for myasthenia gravis: prognostic factors and long term follow-up

F. Venuta, E.A. Rendina, T. De Giacomo, A.M. Ciccone, G. Della Rocca, G. Antonini, E. Guarino, C. Ricci and G.F. Coloni
University of Rome 'La Sapienza', Department of Thoracic Surgery, Policlinico Umberto I, Rome, Italy

Thymectomy is considered a useful therapeutic option for patients with Myasthenia Gravis (MG). We reviewed our 25-year experience with this procedure with respect to long term outcome and analysis of prognostic factors. Between 1970 and 1996 we performed 218 thymectomies for MG. 15 patients were lost to follow up; the remaining 203 (126 females and 77 males; mean age 36·2 years) form the object of our study. 56 patients (27·6 per cent) had a thymoma. MG was graded according to the Osserman classification: 50 stage I (24·6 per cent), 79 stage IIA (39 per cent), 48 stage IIB (23·6 per cent), 20 stage III (9·9 per cent) and 6 stage IV (3 per cent). Mean duration of symptoms before the operation was 11·9 months (0·5–42 months). All thymectomies for thymoma were performed through a median sternotomy; 46 thymectomies for non thymomatous myasthenia were performed through a standard cervicotomy and the other 101 procedures were performed through a partial upper sternal-splitting incision; with this approach the resection could be extended to all the perithymic medistinal fat tissue. Operative mortality was 0·99 per cent (2 patients). Mean hospital stay was 6·4 days (7·9 days before 1980 and 4·8 after 1980). After a mean follow-up of 119 months (6 to 324 months) 67 per cent of all patients improved their clinical status (21 per cent without medications and asymptomatic; 46 per cent with reduction of medications and clinically improved by at least one stage of the Osserman classification). Favourable prognostic factors were lower stage of myasthenia, absence of thymoma, younger age and short duration of the disease. Thymectomy was effective also in patients with ocular myasthenia gravis. Thymectomy presents minimal morbidity and is effective in the management of patients with mysthenia gravis at all stages of the disease. Patients with thymoma present a less favourable outcome.

Expression of MIB-1 and the retinoblastoma gene product in thyroid tumours

F. Barreiro, J. Cameselle-Teijeiro*, J. Moldes*, R. Conde, E. Mena and J. Potel *Departments of Surgery and *Pathology, Complexo Hospitalario Universitario de Santiago 15701 – Santiago, Spain*

Background: MIB-1 is an antibody that reacts with a human nuclear proliferation-associated antigen (Ki-67 molecule), which is expressed in all cells that are not in the G0 phase of the cell cycle. MIB-1 expression is known to be related with the prognosis of numerous malignancies. Alterations of the retinoblastoma (Rb) tumour supressor gene and its encoded protein (RbP) have been detected in a variety of neoplasms. The aim of this study was to assess the expression of MIB-1 and RbP in several types of thyroid tumours and to analyse their interrelationships.
Materials and methods: We evaluated follicular adenomas (FA) (*n*=5), Hürthle cell adenomas (HA) (*n*=5), papillary carcinomas (PC) (*n*=5), follicular carcinomas (FC) (*n*=5) Hürthle cell carcinomas (HC) (*n*=3) medullary carcinomas (MC) (*n*=5) and undifferentiated carcinomas (UC) (*n*=5). The analysis was carried out by the streptavidin-biotin peroxidase complex on formalin-fixed paraffin-embedded tissues using monoclonal antibodies to MIB-1 (Immunotech, Marseille, France, 1:20) and human RbP (G3-245, BioGenex, San Ramon, CA, U.S.A., 1:200). For each case, a percentage of positively staining nuclei for MIB-1 and RbP was obtained by visual quantitative assessment of at least 200 neoplastic cells. Stromal and lymphoid staining were excluded from the counting process.
Results: The results (mean±standard deviation) were:

	FA	HA	PC	FC	HC	MC	UC
MIB-1	1·75±0·92	2·03±1·16	4·27±2·78	10·85±12·91	6·83±4·71	1·84±1·61	37·66±28·21
RbP	49·92±13·94	25·29±11·55	45·67±10·77	18·58±16·65	25·73±33·0	3·17±1·67	43·99±23·45

Statistically significant differences for MIB-1 (*P*=0·006) and RbP (*P*=0·005) were found comparing the several types of thyroid tumours but, the MIB-1 and RbP correlation was not statistically significant (R of Pearson=0·020, *P*=0·272).
Conclusions: These results support the idea that the retinoblastoma gene is implicated in different ways in the various types of thyroid tumours. However, alterations in the expression of the retinoblastoma protein is not related to the proliferation activity of the thyroid tumours.

Supported by grants XUGA20802A96 and FIS-97/0173 Spain.

Localization studies in patients with primary hyperparathyroidism

Cs. Berczi, G. Lukács and Gy. Balázs *1st Department of Surgery Medical University School, 4012 Debrecen, P.O. Box 27, Hungary*

A retrospective study was performed to evaluate the effects of different preoperative localization techniques in patients with primary hyperparathyroidism (HPT).

48 patients underwent parathyroidectomy with primary HPT. Preoperative studies were carried out in all patients. Ultrasound (US) examination was performed in 27 cases, computed tomography (CT) in 15 patients, magnetic resonance imaging (MRI) in 13 cases, and Technetium-99m-sestamibi/Technetium-99m-pertechnetate radionuclide scintigraphy in 23 patients. 48 initial explorations and 4 reoperations were performed. A meticulous bilateral neck exploration was carried out in each patient for the identification of the 4 parathyroid glands. If parathyroid adenoma was diagnosed by frozen-section, exstirpation was carried out. If diffuse hyperplasia was diagnosed, subtotal parathyroidectomy (3 1/2) was performed.

28 of 48 patients with primary HPT had a solitary adenoma, and 1 of 48 patients had a double adenoma. 18 of 48 patients had diffuse hyperplasia of the parathyroid glands. In one patient the histological examination showed parathyroid cancer. 45 of 48 patients (94 per cent) were normocalcaemic after parathyroidectomy. One patient underwent early reoperation with removal of an ectopic gland from the mediastinum. Persistent HPT occurred in 1 patient, and recurrent HPT was noted in 2 patients. In these cases late secondary operations were performed. Sensitivity of localization studies in patients with primary HPT in our series were the following: US 74 per cent (20 of 27 cases), CT: 73 per cent (11 of 15 cases), MRI: 40 per cent (6 of 13 cases), radionuclide scintigraphy 91 per cent (21 of 23 cases).

In conclusion, the highest sensitivity rate of the preoperative localization techniques were found with the Technetium-99m-sestamibi/Technetium-99m pertechnetate scanning. The application of this radionuclide scintigraphy in combination of bilateral neck exploration can improve the cure rate, and decrease the incidence of persistent and recurrent HPT.

Parathyroidectomy for renal hyperparathyroidism: the transplant surgeon's perspective

D. Bowrev, G. Morris-Stiff, R. Lord and W.A. Jurewicz
Department of Transplant Surgery, University Hospital of Wales, Cardiff

Aim: Up to ten per cent of patients receiving renal replacement therapy will require parathyroidectomy for secondary hyperparathyroidism. The aim of the current study was to report the management of this condition by a regional transplant unit.
Patients and methods: Between November 1994 and September 1997 thirty-four patients underwent parathyroidectomy for secondary hyperparathyroidism. The study population consisted of 20 male and 14 female patients of median age 41 years (range 10–63). Renal replacement therapy was as follows: transplant (*n*=17), haemodialysis (*n*=10) and peritoneal dialysis (*n*=5). Two patients were pre-dialysis. Twenty seven patients underwent subtotal parathyroidectomy and 7 patients had a total parathyroidectomy with re-implantation.
Results:

		Pre-operative Median (IQR)	Post-operative Median (IQR)	Statistical significance
Calcium (mmol/l)		3·03 (2·86–3·25)	2·39 (2·19–2·52)	*P*<0·05
Parathormone (pmol/l)		133 (99–150)	3·4 (0·9–11·1)	*P*<0·05
Alkaline phosphatase (IU/ml)		181 (121–237)	103 (63–152)	*P*<0·05
Symptoms	Bone pain (%)	17 (50%)	2 (6%)	*P*<0·05
	Pruritus (%)	9 (26%)	2 (6%)	*P*<0·05

At a median follow-up time of 12 months (range: 1–33) all patients are normolcaecaemic. All patients with functioning grafts have normal parathyroid hormone (PTH) levels however six on haemodialysis have mildly elevated PTH (0 per cent vs. 35 per cent, *P*<0·05).
Conclusion: Parathyroidectomy is effective in correcting the calcium biochemistry dysfunction seen in patients with chronic renal failure. Patients with renal transplants have a superior outcome compared to those on dialysis.

Diagnostic procedures and surgical treatment for insulinoma

P. Chirletti, R. Caronna, G. Tamburrano*, M. Mellozzi*, A. Bonifacino, P. Sammartino, A. Bovino and V. Stipa *Surgical Pathology IX, Surgical Clinic I, *II Endocrinological Department, University of Rome 'La Sapienza' – V. del Policlinico, 00161 Rome, Italy*

Aim of the study: In a retrospective study we analysed the efficacy of preoperative and intraoperative diagnostic procedures for detecting insulinoma and reviewed the surgical procedure in a series of 30 consecutive patients.
Material and methods: Thirty patients (14 men, 16 women, mean age 43·7, January 1988–March 1997) underwent preoperative diagnostic procedures to localize the insulinoma: ultrasonography (US) in 19, computed

tomography (CT) in 23, magnetic resonance imaging (MRI) in 24, selective angiography in 8, arterial stimulation venous sampling (ASVS) and Octreoscan in 21 cases. Most patients (28/30) underwent intraoperative ultrasonography. To determine the sensitivity and diagnostic accuracy of the preoperative and intraoperative localizing procedures, including surgical palpation, we compared these findings with the surgically-proven site of the insulinomas. Twenty-three patients underwent tumour enucleation, 6 distal pancreatic resections and one multiple hepatic biopsies. In the last two patients who underwent enucleation of insulinoma of the pancreatic head, we protected the resection site with a jejunal loop.
Results: In 28 (93·3 per cent) of the 30 patients with clinically-suspected pancreatic insulinoma the tumour was found at surgery. In one patient laparotomy disclosed liver micrometastases without a palpable pancreatic neoplasm. In another patient a hyperplastic lymph node had been mistaken for a tumour. Preoperative US, CT, selective angiography and MRI sensitivity was respectively 5·2 per cent, 18·1 per cent, 28·5 per cent and 78·2 per cent. ASVS achieved the best overall preoperative diagnostic results (sensitivity and diagnostic accuracy 90·4 per cent) whereas Octreoscan achieved only 68·1 per cent diagnostic accuracy. Surgical palpation identified 29 of 30 growths: two were false positive results (a cyst in the pancreatic head and a lymph node in the tail): therefore yielding 93·3 per cent diagnostic accuracy. Intraoperative ultrasonography (IOUS) localized 26 of 28 tumours (sensitivity 96·1 per cent) with one false positive result (diagnostic accuracy 92·8 per cent). Operative mortality was 3·3 per cent and morbidity 23·3 per cent (26 per cent in the group of patients treated with tumour enucleation).
Conclusions: These findings confirm that no single diagnostic imaging modality is reliable for localizing insulinoma. We therefore suggest the combined use of MRI, ASVS and IOUS. In our experience what is radiologically visible may not be palpable; what is radiologically visible and palpable may not be the tumour, and tumours may be neither radiologically visible nor surgically palpable. ASVS provides particularly useful information that helps the surgeon to plan the manual palpation and intraoperative ultrasonography.

Quality control in thyroid surgery: the concept of invasivity

R. Gruber and J. Schumann *Chirurgishche Klinik, St. Marienkrankenhaus, Richard Wagner-Str. 14, D-60318 Frankfurt, Germany*

Is a short, targeted measure less invasive than a prolonged, exploration? In what way does routine thyroid surgery do any functional harm to the parathyroid glands? In this self-assessment approach referring to oncoming quality control standards, four comparably experienced surgeons working with different strategic approaches were given 'points' on an ordered scale of so-called 'invasivity', while doing 100 routine, non-selected, non-randomized thyroid operations in a clinic with good endocrine surgery experience (600–800 thyroid-related operations per year). In a second step, a simple invasivity index was made up: We considered: Invasivity score = 'points' × (volume of thyroid pre OP) × 1/(volume of thyroid post OP) × S for sex, with S=1 if female or 2 (male). This score was then correlated to calcium levels pre- and post operation.

There was no significant correlation between score and eventual postoperative calcium depression. 'Invasivity' did not seem to affect the postoperative calcium regulation.

We propose to discuss the definition of surgical invasivity in the intention to postulate good parametric quality control approaches in endocrine surgery.

Adrenal incidentalomas: criteria for endoscopic removal

L.A. Michel[1], L. de Cannière[1], E. Hamoir[2], G. Hubens[2], M. Meurisse[2], J.P. Squifflet[2] [1]*Surgical Services, Mont-Godinne University Hospital, Yvoir B-5530, Belgium;* [2]*Belgian Group for Endoscopic Surgery, Rue St Georges, 13, B-7181 Feluy, Belgium*

Objective: Adrenalectomy is not a frequent operation. Therefore the newly developed laparoscopic approach is sporadically performed by surgeons dealing with endocrine disorders. We report the results of a multicentric survey and analyse the criteria followed to decide which 'non-functioning' adrenal tumours, discovered incidentally (the so called *incidentalomas*) are to be removed. The criteria being: 1) non-secreting adrenal lesion; 2) diameter larger than 4 cm or increase in size at any re-evaluation; 3) CT scan picture of intratumoral necrosis, haemorrhage or irregular margins; 4) high dehydroepiandrostenedione (DHEAS) level.
Material and methods: Prospective evaluation of 65 videoendoscopic adrenalectomies performed on 63 patients by four surgical teams from the Belgian Group for Endoscopic Surgery (BGES) between October 1993 and October 1997.
Results: Indications for endoscopic adrenalectomy were pheochromocytoma (*n*=23), primary hyperaldosteronism (*n*=18), Cushing's adenoma or disease (*n*=7), single metastasis from adenocarcinoma (*n*=3), adenoma with DHEAS or cortisol hypersecretion (*n*=3), ACTH secreting metastases from a thymoma (*n*=1), non-secreting adenoma (*n*=8). Of the 65 adrenalectomies performed, 36 were of the left gland, 25 of the right and two bilateral. Laparoscopic adrenalectomy was successful in 61 patients (97 per cent). Median tumour size was 4 cm (range 1·5–12), median operation duration 100 minutes (range 59–360), median postoperative stay 4 days (range 2–13). Only one patient required blood transfusion.

Adhering to the proposed criteria allowed us to identify correctly 88 per cent of clear cut indications for adrenalectomy i.e., pheochromocytoma, Conn and Cushing syndromes, high DHEAS and tumours (sensitivity 100 per cent, positive predictive value 87 per cent, accuracy 88 per cent). The incidence (13 per cent) of rather debatable indications (i.e. incidentalomas) in the current series is low compared with other recent large series.
Conclusions: Endoscopic adrenalectomy can safely be performed – even sporadically – by surgeons well versed in adrenalectomy techniques for endocrine disorders and trained in endoscopic surgery. Criteria proposed to decide which incidentalomas are to be operated allow to reduce the debatable indications for adrenalectomy to 13 per cent (8/63).

Analysis of the ret proto-oncogen in families with multiple endocrine neoplasia type 2A

R. Palasi, C. Orellana, E. Castillo, J.L. Ponce, F. Martinez, R. Estevan, F. Prieto, S. Gil, S. Sancho Fornos and R.P. Giménez *Servicio de Cirugía General y Digestivo I. Unidad de Genética, Hospital La Fe, Avda Campanar, 21. 46009 Valencia, España*

Introduction: Multiple endocrine neoplasia type 2A (MEN 2A) is an autosomal dominant genetic syndrome characterized by medullary thyroid carcinoma, phaeocromocytoma and hyperparathyroidism. The application of linkage analysis led to the linkage of MEN 2A to a centromeric chromosome 10 locus and recently specific mutations in exon 10 and 11 of the RET proto-oncogen have been identified in this syndrome. The objective of this study is to evaluate clinical screening as compared with DNA analysis in diagnosis of MEN 2A in 6 families treated in our hospital.
Methods: Forty-six members of six families with MEN 2A were screened for RET proto-oncogen exon 10 and 11 mutations.

- DNA was extracted from peripheral blood samples
- Exons 10 and 11 were amplified separately by polimerase chain reaction (PCR)
- Detection of mutations by single strand conformation polymorphism (SSCP)
- Analysis of the sequences using ABI-PRISM Dye Terminator.

Results: Twenty-five individuals had mutations of codon 634, whereas 21 unaffected individuals had no abnormalities. Five of 25 individuals were of unknown status. Four of these children had thyroidectomy based on this analysis and were found to have medullarr carcinoma.
Conclusions: We concluded that RET mutational analysis is a cost-effective and accurate method for determination of gene carrier status in MEN 2A. The advantages of genetic screening to predictive testing led to substantial changes in carrier risk for many individuals we tested, which suggest that DNA analysis should be introduced in the screening programme of MEN 2A families, bringing many advantages in comparison with traditional biochemical test.

Our experience in genetic screening for multiple endocrine neoplasia type 1

R. Palasi, C. Orellana, F. Martinez, J.L. Ponce, E. Castillo, R. Estevan, J. Brazales, F. Prieto, S. Sancho Fornos and R.P. Giménez *Servicio de Cirugía General y Digestivo I. Unidad de Genética, Hospital La Fe, Avda Campanar, 21. 46009 Valencia, España*

Introduction: Multiple endocrine neoplasia type 1 (MEN 1) which is also referred to as Wermer's syndrome is an autosomal dominant familial disorder characterized by tumours in parathyroid glands, pancreatic islet cells and the anterior pituitary. In addition to these tumours, adrenal cortical, carcinoid and lipomatous tumours has also been described. Screening in MEN 1 is difficult because the clinical and biochemical manifestations in members of any one family are not similar, and because of age related penetrance. In order to improve this situation biochemical screening tests need to be repeated periodically in all the members of the family.

In recent years, important advances in endocrinology have resulted from the application of molecular biology. Application of these techniques have made it possible to localize in chromosome 11q13 the gene causing MEN 1.

Material and methods: We have studied 26 patients from an affected family, 15 women and 11 men, all presenting with hyperparathyroidism. 50 per cent with cortical adrenal tumours, in four cases presenting with pancreatic tumours and in two, anterior pituitary tumours.

This is the method we have used:

- DNA was extracted from peripheral blood.
- Use of PCR (polimerase chain reaction) RFLP's (restriction fragment length polymorphism) and microsatellite polymorphism as genetic markers.
- Segregation analysis to establish MEN 1 haplotype.
- Indirect diagnosis of gene carriers depending on the haplotype inheritance.

Results: We observed an association between the MEN 1 haplotype in this family in all the known affected patients and in the last generation 8 young members of the family presented with the same haplotype and are considered as gene carriers.

Conclusions: These DNA studies enable carriers of the mutant MEN 1 gene to be detected within a family and thereby identify those individuals who need to undergo repeated screening test for the development of tumours. This technique has substantially altered the screening strategy. DNA analysis should be introduced in the screening programme of MEN 1 families.

Multimodal treatment of bony metastases in differentiated thyroid cancer

L. Pezzullo, C. Caracò, F. Fazioli, N. Salati, F. Ionna and N. Mozzillo *National Cancer Institute, 'Fondazione G. Pascale', Via M. Semmola, 2, Naples, Italy*

Bone metastases (BM) from differentiated thyroid cancer (DTC) are a rare event, but represent an adverse prognostic factor with a potential fatal course. The standard modality of treatment consisting of total thyroidectomy (TT) followed by radioactive iodine therapy (RIT) is often not curative.

Of 174 patients with DTC seen in our Division from January 1992 to June 1997, 17 (9.7 per cent) had BM in one case with associated lung involvement. There were 14 females and 3 males with mean age of 60·1 years (range 39–74), but only 6 patients were under 60. TT was performed as the initial operation in 13 cases, one also underwent a unilateral neck dissection for clinically evident cervical node involvement. In addition one patient had simultaneous rib resection for a huge BM. Three patients, having previously undergone partial thyroidectomy in other institutions, years before, for conditions classified as benign, were referred to us for completion thyroidectomy and treatment of multiple BM. One patient with locally advanced DTC, diagnosed by fine needle aspiration biopsy, could not be operated on for severe cardiovascular disease and had been treated by RIT alone. Seven patients presented neoplastic fracture, five with a femara and two humera respectively. Of these patients, four had been submitted to bone replacement with metal prosthesis after one or more treatments with RIT, the others, not suitable to major surgery, were treated with intramedullary nailing and RIT. 12 patients presented BM simultaneous to DTC, while 5 developed BM years after the primary procedure, none of these patients had the correct diagnosis at the time of primary operation, multiple bone involvement was present. Histological examination of resected specimens, showed follicular carcinoma in 10 cases (58 per cent), insular cancer in 2 patients (11 per cent), Hurtle cell carcinoma in 2 patients (11 per cent) and 2 cases of papillary cancer (11 per cent) with a case of tall cell variant. In 1 case the histological diagnosis was unknown. The survival rate was very low, 3 patients died within a mean of 31 months after the diagnosis. The others are alive, mostly with disease after a mean follow-up of 21 months. From the analysis of this series, we conclude that BM from DTC carries a poor prognosis and new modalities of therapy may be needed. At the present time the surgical treatment of the bone lesion, whenever possible, followed by RIT is the treatment of choice for all patients.

Multiple endocrine neoplasia type 2A. Study of 96 members of 5 families

J.M. Ponseti, E. Espin, J.L. Sanchez, C. Vicens and M. Armengol *Department of Surgery (Prof. Armengol), Hospital General Universitario Vall d'Hebron, Universidad Autonoma de Barcelona, Spain*

Multiple endocrine neoplasia type 2A (MEN 2A) is an autosomal dominant inheritance disease, characterized by the occurrence of medullary thyroid carcinoma (MTC), pheochromocytoma and hyperparathyroidism. Increased calcitonin hormone (CT) indicates C-cell disorder. Annual testing of family members, with stimulus of CT secretion by calcium and pentagastrin, has been used routinely for diagnosis of the tumour for many years. This procedure is associated with bothersome side effects, and some family members have refused repetitive testing. After 1987 the genetic analysis of chromosome 10 was introduced and presymptomatic prediction of disease susceptibility became feasible by indirect test and latter direct predictive test by study of the mutations in the RET protooncogene. Family members who had RET mutation would be candidates for thyroidectomy and members without RET mutation could be assured that neither they nor their descendants would develop the disease.

Material and methods: Between 1974 and 1997 we studied 96 members of 5 families, 47 of them accepted the annual test for detecting elevated CT, 15 of them were operated upon for MTC (group A). After 1990 we started the study of the RET protooncogene mutation in 20 members with 12 positives (group B). During these 22 years we performed 27 total thyroidectomies with central zone lymph node dissection, 10 unilateral cervical lymph node dissection and one bilateral cervical lymph node dissection. Before thyroidectomy we performed 9 adrenalectomies for pheochromocytomas and one subtotal parathyroidectomy with forearm autotransplantation (Well's operation) for hyperparathyroidism. A total of 29 patients of the 5 families refused any study.

Results: We found that in group A (CT), 15 patients with MTC had elevated CT levels, between 720 and 10000 pg/ml, with a mean of 6600 pg/ml (normal <250 pg/ml). 11 patients had macroscopic tumour, 3 microscopic and 1 hyperplasia of C cells, 10 of them were lymph node positive. During postoperative follow-up, 8 deaths from metastases were seen and 2 had elevated postoperative CT levels. In group B (genetic study) 12 had elevated CT levels between 180 and 3500 pg/ml mean 930 pg/ml, 5 patients had macroscopic tumour, 5 microscopic and 2 had hyperplasia. Positive lymph nodes were observed in 5 cases. When we reject the so called 'guide patients' in the genetic group, we found only 1 patient with macroscopic tumour, 5 with microscopic tumour and 2 with hyperplasia. Only one patient had positive lymph nodes. In the postoperative follow-up we had only one patient with elevated CT. Of the 20 case with genetic study, eight members were negative and were eliminated of the study along with their descendants.

Conclusions: In our patients, we found the genetic study for detection of presymptomatic cases of high value because it gives the possibility to exclude members of the kindred without disease and improves the success rate for affected members. Some members refused any test for prediction of disease.

Reconstruction of the external ear throughout radial forearm fasciocutaneous free flap

Al.V. Georgescu, O. Ivan, Z. Donca and C. Melincovici *Clinic of Plastic Reconstructive Surgery, University of Medicine 'Iuliu Hatieganu', Spitalul Clinic de Recuperare, 3400 Cluj-Napoca, Str. Viilor Nr. 46–50, Romania*

General approach: The absence – congenital or post-traumatic – of the external ear may produce an important aesthetic discomfort.

In practice there are several methods of reconstruction most of them usually using the temporal skin.

In cases of skin with multiple scars, some other method of reconstruction must be found.

Material and method: The case of a 27-year-old patient with post-traumatic absence of the entire right external ear is presented here. The scars in the area made impossible the use of the skin for reconstruction.

Reconstruction of the external ear by using a free microsurgical transfer of radial forearm fasciocutaneous flap was performed.

After the integration of the flap, modelling with silastic was accomplished in several consecutive stages.

Results: The immediate evolution of the flap was very good with its complete integration.

In the long term, after modelling, we succeeded in obtaining an acceptable external ear in both form and dimensions.

In conclusion, we presume that the technique used could be regarded as a possible new technique for reconstruction of the external ear.

Parotid adenolymphoma: improving preoperative diagnosis and subsequent surgical management

D.R. Lewis, A.J. Webb and J.R. Farndon *Bristol University Department of Surgery, Bristol Royal Infirmary, Bristol, United Kingdom*

Aim: This study (1985–1995) reviewed the role and results of FNAC in the diagnosis of adenolymphoma and examined methods of improving these results.

Methods: Review of cytological smears paid particular attention to features of infarction and squamoid metaplasia. Case note review concentrated on controversies in surgical management.

Results: Of 222 epithelial neoplasms of the parotid 33 were adenolymphomas. FNAC was performed preoperatively in 32 and a correct cytological diagnosis was made in 22 patients. Retrospective review of cytological material, taking into account the new specific features of squamoid metaplasia and infarction, improved this to 31 patients having cytological smears suggestive or diagnostic of adenolymphoma.

			%	95% CI
Definitive Report	Diagnostic of adenolymphoma	21/32	65·6%	0·47–0·81
	Diagnostic and suggestive results combined	24/32	75%*	0·57–0·89
Retrospective Report (AJW)	Diagnostic of adenolymphoma	25/32	78·1%	0·60–0·91
	Diagnostic and suggestive results combined	31/32	96·8%*	0·84–1·0

(*P=<0·05 McNemar test)

CE was performed in 12 patients and superficial parotidectomy in 11. Ten other operations were described. Of the three patients with postoperative facial nerve weakness and two with Frey's syndrome, none were related to CE. There were no tumour recurrences.

Conclusion: Squamoid metaplasia and infarction are well documented, though seemingly often ignored, features of parotid adenolymphoma. Attention to these aspects improves cytological diagnosis and allows better directed surgical management.

Percutaneous sclerotherapy of idiopathic varicocele in childhood. Review of 27 cases

Ch. Grapin*, F. Fayad* and N. Sellier** *Departement of Pediatric Surgery; **Department of Radiology, Hopital Jean Verdier 93140 Bondy, France

Management of left idiopathic varicocele in childhood is widely accepted to prevent testicular damage. Surgical techniques are often disappointing, with high recurrence rate in relation with anatomical variations (collateral and anastomosis).

Percutaneous sclerotherapy seems to offer better results (sclerosis of varicocele itself and control of run-off via collaterals).

During a period of four years, 27 patients aged nine to 16, with left sided idiopathic varicoceles, grade II or III according to classification of Dubin and Amelar, were treated by percutaneous retrograde sclerotherapy of the left internal spermatic vein.

Under local anesthesia and with fluoroscopic control, a co-axial catheter 5-F is introduced via the right femoral vein into the left renal vein (Seldinger method). 3 to 6 cc of sclerosing agent are injected into the testicular vein and its collaterals. After removal of the catheter, the patient is kept under observation for 3 hours.

No major complication was observed. Clinical and sonographic review occurred at 3, 6, 12 months. Follow-up ranged from 1 to 7 years (mean 34 months).

The sclerotherapy was performed in 26 boys (feasibility rate 96·3 per cent). Two boys showed persistent varicoceles at 3 months (persistent rate: 7·4 per cent) but repeat sclerotherapy was performed successfully. Three of four boys (75 per cent) with testicular volume loss demonstrated testicular catch-up growth in the first year of follow-up.

Finally, all varicoceles were occluded after one ($n=24$) or two ($n=2$) sessions.

In conclusion: Percutaneous sclerotherapy under local anesthesia proved to be an efficient and convenient treatment of varicocele in childhood.

Postoperative emergency attendance and hospital stay in day care coloproctological surgery

D. Huerga, M. Vilches and A. Payno *Fundación Jiménez Díaz, Servicio de Cirugía General y del Aparato Digestivo, Sección de Coloproctologia, Avda, Reyes Católicos, 2. 28040 Madrid, Spain*

The necessity to stay in hospital after an operation and to represent to the Emergency department on the following days are concerns in Day Surgery. During the first year of experience in our Unit of Major Day Surgery, these situations have been analysed in Coloproctologic Surgery, to study the causes and try to minimize them, also as a quality indicator of our activity.

Material/methods: A prospective follow-up of all patients operated in our unit has been designed. During the first year (October 1996–1997) we performed 379 coloproctological procedures distributed as follows: 133 haemorrhoidectomies, 75 fissures, 67 fistulas, 29 pilonidal sinus, 28 condylomas, 8 abscesses, 2 hidradenitis and 31 miscellanies.

A prospective follow-up of all the patients have been performed, and the results have been analysed.

Results: Four patients (1 per cent of the total) remained in hospital after surgery. One of them, a fistulectomy, because of bleeding. The other three (haemorrhoidal operations) because of excessive pain.

14 patients came to the Emergency Department on the days after surgery (37 per cent), most of them because of bleeding. For each procedure the frequencies of emergency visits were as follows: 6 hemorrhoidectomies (4·5 per cent), 5 fistulas (7 per cent), 2 abscesses (25 per cent), 1 condyloma (4 per cent) and 1 pilonidal sinus (3 per cent). No statistic significant differences were found in this distribution of frequencies, but the Logistic Regression Analysis shows a major relative risk (6 times higher; $P=0{\cdot}0475$) of Emergency attendance in abscesses and a statistical trend of major risk (around 1·4) in fistulas, compared to hemorrhoidal procedures.

Age and anesthetic procedure had no demonstrable influence in hospital stay after surgery nor in emergency attendance.

Conclusions: Between 2·11 per cent and 6·27 per cent of patients require emergency attendance after coloproctological day surgery ($P<0{\cdot}05$) for several reasons.

Between 0·52 per cent and 2·87 per cent ($P<0{\cdot}05$) of patients need to remain in hospital, mostly because of pain. The risk of requiring postoperative emergency attendance in abscess surgery is six times higher than in haemorrhoids.

The importance of a day-surgery unit in the organization of the activity of a specialistic surgical division

S. Sandrucci, F. Trombetta, C. Zanon, M. Deandrea, F. Aprà, P. Raviola, R. Moscato, M. Rizzo, F. Moro, L. Roy, A. Pourshayesteh, B. Mussa and A Mussa *Oncological and Oesophageal Surgery Section, University of Turin, Day Surgery Unit, Cso Dogliotti 14 10126 Torino, Italy*

Aim of the study: The availability of a day hospital facility with independent beds has allowed us to activate a day-surgery unit, according to the day ward model with dedicated theatre (RCS. Guidelines 1992). The aim was to treat intermediate pathologies with efficiency and effectiveness without slowing down the activity dedicated to complex cases.

Materials and methods: From March 1994 to December 1996, 814 interventions in day surgery have been performed. At the Day Surgery Unit of our institution (281 hernial tension-free repairs, 301 oncological surgical procedures and 224 proctology, phlebology, general surgery and urology interventions). The organisational protocol schedules a first day care selection visit, a day-hospital admission with two programmed visits [a) preoperative evaluation and b) the day of surgery] and a follow-up visit. 720 cases have been subjected to infiltration anesthesia with 1 per cent buffered Mepivacaine or Lidocaine. Spinal anesthesia has been mainly used for proctological and phlebological interventions in 63 cases, while a locoregional block (according to Winnie) has been performed in 25 cases.

Results: We observed 33 complications among 814 treated patients (4·1 per cent): hematomas, seromas and infection, these latter observed in less than 0·5 per cent of cases. One patient from 814 (0·1 per cent) has been submitted to general anaesthesia for intolerance of the treatment; seven patients have been converted from the treatment in the day hospital to ordinary hospitalization. The mean duration of hospital stay has been of 3·5 hours; with no significant differences between the different analysed groups. 97 per cent of patients have been totally satisfied by the experience, and 2·5 per cent partially satisfied. Only four patients have formulated a completely negative judgment, probably bound to bad or incomplete information about the procedure.

Conclusions: The high percentage of satisfaction and the low rate of complications show that the organizational model of day surgery is optimal to integrate the treatment of average complexity pathologies in the activity of a specialistic department.

Complicated varicose vein surgery in a Hungarian private day-case unit

T. Szabó and Zs. Varga *Varix Klinika KFT, Szélsö sor 3. H-6728 Szeged, Hungary*

The aim of this study is to show that even complicated varicose vein surgery can safely be performed as day surgery in a country where this does not have a tradition.

Strict diagnostic and therapeutic protocol was followed. A continuous wave (CW) Doppler investigation was done in every case after physical examination and phlebography was performed for lesser saphenous vein (LSV) incompetence. Complications such as leg ulcers or superficial thrombophlebitis did not, but American Society of Anaesthesiologists (ASA) class 3 unstable or worse physical status did contraindicate day care surgery.

Between 1992 and 1997 551 extremities of 457 patients (99 men, 358 women) were operated on. The mean age was 45 years (range 17–83). At the time of surgery 35 patients (six per cent) had venous ulcer, 62 (11 per cent) had venous eczema or liposclerosis. Twenty-four procedures (4 per cent) were performed for acute varicophlebitis, out of them six had thrombi floating into the deep vein. The standard surgical procedure was high ligation of the greater saphenous vein (GSV, 496 extremities), LSV (32 extremities), or both (23 extremities), stripping and stab incision avulsion varicectomy. Surgery was performed under local anaesthesia, completed with sedatives. The standard hospital stay was 10 hours. Only two patients (0·36 per cent) had to be hospitalized for blood pressure disturbances for 24 hours. There was no need for hospitalization for surgery related complication. The only wound infection (0·18 per cent) was treated successfully on an outpatient basis.

Our results: total postoperative morbidity 0·9 per cent, ulcers healing within 8 weeks, no wound infection after surgery for venous ulcers, immediate pain relief in varicophlebitis, shows, that even complicated varicose vein surgery can be performed safely on an outpatient basis.

Audit of the value of a trauma team in a District General Hospital

F.G. Bergin, M.M. Lambertz, I.L. Rosenberg and D.J. Leaper
North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

Aim of the study: To provide early appropriate assessment, resuscitation and intervention of patients following trauma with early referral for specialist treatment; to audit patient numbers, clinical performance and resource management together with continuing education of trauma care staff.
Materials and methods: Between January 1994 to June 1997 422 patients presented to Accident & Emergency necessitating callout of the defined trauma team (a representative of surgery, orthopaedics and anaesthetics). A more detailed audit involving 55 patients presenting over the latter six months of this audit showed that 46 (85 per cent) had a Revised Trauma Score (RTS) of 12. There were four seriously injured patients (RTS<10) one of whom died. Most patients presented with blunt trauma (road traffic accidents or falls); there were 3 patients who presented with penetrating injuries.
Summary of results: 32 patients (59 per cent) were seen by the complete trauma team within 5 minutes; all but one were seen within 20 minutes. All these data are submitted to the Major Trauma Outcomes Study (MTOS).
Conclusions: The volume of severe multiple injured patients is small but the trauma team call out system ensures early and complete triage but is demanding of resources. Further audit has shown that calls put out between 11pm–9am are as safe, relying on triage by Accident & Emergency staff alone during daytime hours.

Undetected pancreatic trauma in patients with severe abdominal trauma

S.A. Carnazzo, S. Emmi, M. Scravaglieri, A. Di Stefano and V. Di Benedetto *Cattedra di Patologia Speciale Chirurgica C.O., Università di Catania, Dipartimento di Emergenza, Azienda Ospedaliera 'Cannizzaro' Catania, Via G. Pezzana, 23, 95021 Acicastello (CT), Italy*

Study: Aim of the study is to evaluate undetected pancreatic complications (UPC) rates in patients operated for severe abdominal trauma (SAT), who had during the post-operative course (POC) symptoms of pancreatic trauma (PT) not demonstrated by pre-operative investigations and during laparotomy.
Materials and methods: 15 patients (12 males and 3 females) with a mean age of 37 years, who had, during the POC, complications related to undetected PT were retrospectively evaluated on the basis of laboratory findings, radiologic studies, early complications and surgical management.
Results: The UPC were hemorrhage in 6 patients (40 per cent), amylase elevations in 4 (26·6 per cent), intraabdominal collection in 2 (13·3 per cent), sepsis in 2 (13·3 per cent) and pancreatic fistula in 1 (6·6 per cent). 14 reinterventions were performed on 9 patients (60 per cent), while 6 (40 per cent) patients were treated conservatively. According to Lucas, the patients were grouped: 5 (33·3 per cent) grade 1; 4 (26·6 per cent) grade 2; 4 (26·6 per cent) grade 3; 2 (13·3 per cent) grade 4.

Complications and mortality rates in these series were respectively 80 per cent and 33 per cent during the second post-operative time.
Conclusions: Our experience shows the incapacity of laboratory findings and radiologic studies to evaluate correctly, during an emergency, pancreatic trauma in patients with SAT. We believe that in uncertain cases, monitoring of amylase and lypase levels in intra-abdominal fluids can help in the management of these critical patients.

Early post-operative diagnosis and early reoperation, in fact; can reduce complications and mortality rates.

The use of nerve supplied fasciocutaneous free flaps for covering soft tissue losses of the foot

Al.V. Georgescu, O. Ivan, R. Onoe, C. Maior, S. Serbu, C. Melincovici and Z. Donca *Clinic of Plastic Reconstructive Surgery, University of Medicine 'Iuliu Hatieganu', Spitalul Clinic de Recuperare, 3400 Cluj-Napoca, Str. Viilor Nr: 46–50, Romania*

General approach: In order for a covering method of the foot's soft tissue losses to be chosen, the surgical team has to take into account the main role the foot has to play in maintaining the posture of the human body. Therefore the flaps chosen must be thick enough, well vascularized and, above all, well innervated. Therein one of the best methods is the use of microsurgical free transfers of nerve supplied radial fasciocutaneous flaps.
Material and method: In the last five years, in our Plastic and Reconstructive Surgery and Microsurgery Clinic from Cluj-Napoca, Romania, this method was used on 37 casualties (31 males and 6 females) aged between 7 and 69 years. 20 of the casualties were acute traumas and the other 17 were post-traumatic or postoperative sequels.

In all the cases a fasciocutaneous forearm free flap based on the vascular radial pedicle and the sensitive branch of the musculocutaneous nerve was used. As source of blood supply for the flaps, the tibial anterior vascular pedicle (in 19 situations) and the tibial posterior vascular pedicle (in 18 situations) was used.
Results: The immediate postoperative evolution was a very good one, including the full integration of the flaps in 35 situations. In the remaining 2 cases, the flaps failed because of venous thromboses.

As for the long term evolution, we have noticed: 1) a very good integration of the flaps; 2) very good and early re-achievement of sense in 32 of the cases, without any ulcerative lesions occurring; 3) in only three of the cases the mediocre re-achievement of sense of the flaps allowed minor ulcers to appear; this problem has been surgically treated and never appeared again.
Conclusions: 1) The use of nerve supplied flaps prevents ulcerative lesions from occurring. 2) If no postoperative complications occur, time and costs of treatment are considerably reduced and the social and professional rehabilitation of the patients is hastened and improved.

Pleuro-pulmonary injuries in thoracic trauma

G.H. Ionescu, I. Lica and F. Iordache *Surgical Department, Emergency Hospital Bucharest, 8 Floreasca Avenue, 71406, Bucharest, Romania*

Aim: Thoracic trauma accounts for approximately 25 per cent of trauma deaths, are recorded at half of the deaths in the multiple injury patients. The aim of this study is to evaluate the results regarding the pleuro-pulmonary consequences in a specific emergency department.
Material and method: This study analysed a total of 374 patients with thoracic trauma either as a single injury or as a part of a multiple injured situations admitted at the Bucharest Emergency Hospital between January 1993–August 1994. Twenty-eight parameters were recorded and analysed.
Results: There was a sex ratio 5:1 (male prevalence). The most frequent parietal lesion was rib fracture. Haemothorax (mostly minimal) was the most frequent situation being recorded in 90 per cent of the cases while pneumothorax was found only in 30 per cent of the patients. Pulmonary injury was found in 32 per cent of the cases. Mediastinum was involved in only 1·8 per cent of the patients. In 10·7 per cent patients a flail chest was recorded. Surprisingly there was no firm correlation with the degree of acute respiratory insufficiency.
Conclusions: In multiple injured patients the most common association for thoracic trauma was with limb injuries (fractures), with head trauma, respectively with abdominal trauma. The thorax-head trauma association was also the highest in terms of mortality. In 11·3 per cent of the cases there were more than two regional injuries. Thoracic trauma either as singe injury or in association remains a crucial clinical item with yet suf-

ficient unresolved problems from which the most important remains the management of the respiratory insufficiency.

Antibiotic prophylaxis in penetrating trauma – a prospective, randomized comparison of a single- vs. multiple-dose regimen

A. Schmidt-Matthiesen, J. Windolf, D. Sommerfeldt, C. Gutt and A. Encke *Department of Surgery, J.W. Goethe University, Theodor-Stern Kai 7, D-60590 Frankfurt am Main, Germany*

Aim: The aim of the study was to analyse whether a single shot antibiotic offers the same antiinfective efficacy as a multiple dose regimen in patients with penetrating trauma. Additionally, the total costs of the anti-infective treatment consisting of the purchase price, the costs of the administration of the medication and the costs of antibiotics given to treat an infection were calculated.

Methods: In the phase IV trial 206 consecutive patients admitted with penetrating trauma of thorax, abdomen or limbs were prospectively randomized to receive a single dose ceftriaxone 2 g (to be given upon admission) or thrice daily cefotixin 2 g for three days (starting upon admission). At admission, 14 per cent of all patients were assessed as having minor trauma, 60·1 per cent moderately severe and 25·9 per cent severe injuries. There were no differences between the treatment groups in respect of postoperative variables. The end point was infection occurring within 10 days. To be included, patients had to have penetrating injury to only one part of the body, reach the hospital within two hours of being injured and receive adequate surgery within 16 hours of being injured. Patients were excluded if it appeared likely that they would require mechanical ventilation for more than 24 hours. Prolonged mechanical ventilation carries the increased risk of pulmonary infection, which could prevent reliable evaluation of antibiotic prophylaxis. The same applies to open or grade II/III craniocerebral trauma. Randomization was stratified for abdomen, thorax and limbs. Statistical analysis was carried out using the SPSS/PC 5.0.2 statistics package, Testimate 5.1.1 and SAS for Windows 6.0. The frequency of infections up to the trial end point was analysed using the Santer CM test for 2×2 field tables. In addition, exploratory t-tests were carried out to obtain descriptive t-values.

Results: 11 patients withdrew from the trial, leaving 97 patients in the ceftriaxone group and 98 in the cefoxitin group. 96 per cent of the ceftriaxone group and 95 per cent of the cefoxitin group remained infection-free. In the ceftriaxone group, one patient developed a superficial infection, another showed clinical signs of infection that could not be localized, one patient developed a late superficial infection on day 20, and another developed superficial infection after reoperation. In the cefoxitin group two patients developed superficial infections, pneumonia was suspected clinically but not confirmed in one patient, and two others developed superficial infection after reoperation. In neither treatment group was deep infection, abscess, phlegmon or sepsis seen. No patient required additional surgery or intensive care due to infection. At $41·83 vs. $172·16, the average costs of delivering medication, including staff time, was significantly lower in the ceftriaxone group ($P<0{\cdot}001$).

Conclusion: When started early, antibiotic prophylaxis with a single 2 g dose of ceftriaxone on the day of injury or thrice daily 2 g cefoxitin for 3 days confers a high degree of protection against post-traumatic infection. Prophylaxis with a single dose of ceftriaxone has considerable practical and economic advantages.

Antibiotic prophylaxis of traumatic lacerations in limb injuries

S. Stamou[2], A. Tsaroucha[1], H. Maltezou, C. Scondras[2] and D. Kafetzis[3] [1]*Astros Health Center;* [2]*Department of Pediatric Surgery and* [3]*Second Department of Pediatrics, 'P.&A. Kyriakou' Children's Hospital, Thivon & Levadias 3 str., GR-115 27 Athens, Greece*

Aim of the study: The need for antimicrobial prophylaxis was examined in 100 patients, with minor limb injury wounds presenting in Astros Health Center.

Materials and methods: 100 patients, 78 males (78 per cent) and 22 females (22 per cent) were prospectively randomized to one of two treatment groups. Patients in group A (n=52) received antibiotic prophylaxis, with 625 mg amoxycillin plus 125 mg clavulanate administered orally, in 3 daily doses, for 4 days. In patients assigned in group B (n=48), no antibiotics were given. All wounds underwent a standard surgical toilet and then were closed under aseptic conditions. Patients' wounds were re-examined for wound inflammation and presence of pus, between 5 and 10 days after suture.

Results: The mean age of patients was 47 years (range: 12–66 years). Patients of both groups did not differ significantly in parameters like gender, age, cause of injury, trauma length, depth and pattern, placement of deep sutures, surgical debridement, as well as factors adversely affecting wound healing, like diabetes mellitus, cancer, use of immunosuppressive agents or corticosteroids. Six patients (12·5 per cent) in group A and 10 patients (20·8 per cent) in group B suffered a wound infection. This difference was found to be statistically non-significant ($P>0{\cdot}10$).

Conclusions: In our study antimicrobial prophylaxis did not reduce wound infection rate in minor limb injury wounds. Routine antibiotic prophylaxis in minor limb injury wounds is discouraged.

Retroperitoneoscopic adrenalectomy from a posterior approach

Á. Balogh, Gy. Lázár, A. Paszt and J. Furák *Department of Surgery, Albert Szent-Györgyi Medical University, 6701 P.O. Box 464, Szeged, Hungary*

A number of conventional techniques are available for adrenalectomy. The rapid development of minimal invasive surgery has reached the adrenal area. The technique of endoscopic retroperitoneal adrenalectomy elaborated in 1995, has not yet become widespread. Our initial experience with retroperitoneoscopic adrenalectomy is described.

Patients and methods: A 32- and a 28-year-old women, both with primary adrenal gland tumours require unilateral adrenalectomy. One of the patients had a phaeochromocytoma, while the other patient had Cushing's syndrome due to an adrenal adenoma. Both tumours were on the left side. The patient with the phaeochromocytoma was prepared with phenoxybenzamine and propranolol. The same operative technique was used as that described by Waltz. The operations were performed under general anesthesia in the prone position. A 1·5 cm skin incision was made just below the tip of the 12th rib. A smaller retroperitoneal cavity under the dorsolumbar fascia was created by blunt digital dissection. Under internal finger guidance, 5 cm laterally a 5 mm trocar and 5 cm medially a 12 mm trocar were inserted. Into the initial incision site, a blunt 10 mm trocar with an inflatable balloon was introduced. Following carbon dioxide insufflation at a pressure of 15–20 mm Hg, the kidney was visualized and the adrenal gland approached near the anteromedial border of the kidney. The gland was dissected and the vessels were divided with an ultrasonically activated scalpel (Harmonic Scalpel, UltraCision, Smithfield, RI). The completely mobilized adrenal gland tumours (2·5 and 5 cm diameter) were removed within an endopouch.

Results: Both procedures were successfully completed. The operating time were 150 and 90 minutes, blood loss was minimal (20–50 ml). There were no intraoperative or postoperative complications. The duration of postoperative hospitalization in both cases was 3 days. Histological examination confirmed the preoperative diagnosis (no evidence of malignancy and complete excision).

Conclusion: Retroperitoneoscopic adrenalectomy is safe and involves less pain and permits a rapid return to normal activity. It may be a preferred method for removing medium-sized (up to 5 cm) unilateral lesions of the adrenal gland.

Impact of diagnostic laparoscopy on the management of acute abdominal pain in young women

M.K. Barry, H. O'Grady, S. O'Neill, D.C. Grant, O. Traynor and J.M.P. Hyland *Department of Surgery, St. Vincent's Hospital, Elm Park, Dublin 4*

Aim: Acute appendicitis accounts for less than 40 per cent[1] of presentations of acute abdominal pain in young women. Non-invasive studies are frequently employed to determine other causes of acute abdominal pain in patients treated conservatively. The aim of this study is to evaluate the impact of diagnostic laparoscopy in the management of acute abdominal pain in women less than 30 years of age.

Method: A total cohort of 130 patients (1991–1997) were included with a mean age of 21·5 years.

Results: At laparoscopy, the diagnosis of acute appendicitis was made in 62 patients (48 per cent). Histology confirmed this diagnosis in 58 (94 per cent). An additional 16 visually normal appendices were removed, six of which contained histologic abnormalities (four acutely inflamed, two fibrosis/obliterated lumen).

Gynaecological causes of pain were found in 37 patients (28 per cent). These included 33 cases of ovarian cysts, 1 infarcted ovary, 1 case of endometriosis and 2 cases of pelvic inflammatory disease. Seven patients had miscellaneous diagnoses and no cause was found in the remaining 8 patients.

Conclusion: Diagnostic laparoscopy is a useful modality in the evaluation of acute abdominal pain in young women. Positive findings may be expected in the majority of patients. Our findings suggest that negative appendicectomies may be reduced using this method.

Adjustable minimally invasive surgery applicator (AMISA) for tissue management

R.Th. Carbon, M. Thais, M. Schreiber and H.P. Huemmer
Department of Ped. Surgery, University Hospital of Surgery, Maximillianspiatz 2, 91054 Erlangen, Germany

Aim: In thoracoscopy and laparoscopy the options for tissue management can be greatly expanded by the use of a collagen bandage coated with components of fibrin glue. This biodegradable tool has proven to be of particular value, and even leads to interesting extensions of indications.

Methods: In experimental surface models the different methods of liquid gluing proved to be fairly unstable, therefore an adjustable MIS applicator (AMISA) for the patch-bound glue was developed which simplified the introduction and placing of the 10×5 cm collagen bandage coated with tissue glue in the appropriate body cavity. Because of the application of such a large patch, not only haemostasis, but also rapid sealing of larger tissue defects in the pleural and abdominal cavities was made possible. To demonstrate the surface stabilizing properties of liquid glues and patch-bound glues, a simulation model with a pressure chamber was built. The pressure at the upper limit was measured. A ready-to-use product of a collagen bandage coated with components of tissue glue was optimal as regards its sealing and gluing properties.

Results: If the experimental results are applied to surgical practice (1994–1997), the selective leak closure (SLC) of the visceral pleura could be used to treat diseases of the pleura and diseases of the pulmonary structures. Pleural leaks, of which 83 were pneumothorax and 11 chylothorax have been treated successfully, in hepatic, biliary, and splenic surgery the collagen bandage was used as a sealant in resections (26), Hodgkin staging (7), closure of biliary fistulas (5) and MIS-management in blunt abdominal trauma (17).

Conclusions: The innovative MIS-application of bandage-bound tissue glue in addition to increasing the number of potential indications, also expanded existing indications. The following endpoints can be defined: increase in the effectiveness of the selected procedure (reduction of draining time), increase in the efficiency (reduction of complications), decrease in intensive care, improvement in psychosocial structure (decrease in hospitalization, improved parent–child relationships).

Short term comparison of laparoscopic antireflux surgery to conservative therapy for reflux oesophagitis

Z. Hajdu and M. Molnar *Department of Surgery/Kenezy Teaching Hospital, University Medical School of Debrecen, Bartok B. U. 2–26, Debrecen 4043, Hungary*

The present study evaluates short term symptomatic and endoscopic outcome in gastroesophageal reflux disease comparing conservative therapy to operative management.

The study comprised 110 consecutive patients referred for reflux syndromes and erosive gastritis confirmed by endoscopy from 1993 to 1994. The patients received conservative management and medication. The oesophageal healing was evaluated by endoscopy. If conservative management failed to relieve symptoms and esophageal healing, laparoscopic antireflux surgery was performed. The patients were followed-up by clinical examinations and interviews/median 4·74 years.

Laparoscopic antireflux surgery was performed in 35 of 110 patients. Results at their follow-up: 32 (91 per cent) had no heartburn, 31 (89 per cent) were free from erosive gastritis, only 1 (3 per cent) was given medication. Corresponding figures in conservative group was 56 (75 per cent), 49 (65 per cent), 16 (21 per cent).

In gastroesophageal reflux disease the laparoscopic surgical treatment gave much more favourable short term results compared to those from conservative therapy.

The safety of laparoscopic cholecystectomy in sickle cell disease

A.-W.N. Meshikhes, H. Al-Abkari, A.A. Al-Faraj and S.A. Al-Dhurais *Departments of Surgery and Medicine, Dammam Central Hospital, Dammam Eastern Province, Saudi Arabia*

Aim: Patients with sickle cell disease (SCD) are at an increased risk of developing pigmented gall stones which require surgical intervention. However, surgery is associated with high morbidity and mortality. Minimally invasive surgery offers an attractive option due to its numerous advantages over the conventional methods.

Materials and methods: From October 1992–December 1996, 71 SCD patients (42 males, 29 females) with gall stones underwent laparoscopic cholecystectomy (LC) which was done electively in 65 patients. Their mean age was 25 (range 13–58) years. 47 patients have had sickle crises ranging 1–10 per year. The symptoms were: upper abdominal pain (65), fatty food intolerance (33), nausea & vomiting (56) and jaundice (12). Five patients were asymptomatic. The mean preoperative haemoglobin was 9 (range 6·3–13·5) g/dl and mean HbF and HbS were 14·5 per cent (range 6·6–33) and 72·4 per cent (range 54–90·9), respectively. Preoperatively, 42 patients received simple blood transfusion (group 1), 13 were given exchange transfusion (group 2) and 16 had no transfusion (group 3).

Results: The mean operative time was 80 (range 40–270) min. Four cases (5·6 per cent) were converted to open. Ten patients (nine from group 1 and one from group 3) developed complications: acute chest syndrome 2, atelectasis 2, chest infections 2, wound infections 2, vasoocclusive crisis 1 and abdominal wall haematoma 1. There was one mortality (group 3) due to vasoocclusive crisis. The median hospital stay was 2·5 (range 1–10) days.

Conclusion: LC can be conducted safely in patients with SCD. Preoperative exchange transfusion is advocated in sickle patients undergoing surgery as it is associated with less morbidity and mortality, but this needs further evaluation.

The effect of total parenteral nutrition on immunological system

N. Akyürek, A. Bedirli, M. Kerek, M. Keçeli and O. Yüksel
Erciyes University, Medical Faculty, General Surgery Kayseri, Turkey

It has been reported that immunosuppression is induced with long lasting administration of total parenteral nutrition (TPN). However, the present clinical status of the patient may be another parameter to affect this situation.
Aim: To investigate the effect of TPN on the immune system of patients unable to feed orally.
Materials and methods: In this study, the effect of TPN on the immunological states of 20 patients who had no oral intake at least for five days were investigated in a randomized fashion. The patients who had received radiotherapy or chemotherapy and who were immune compromized were excluded from the study. T-lymphocyte (CD3+), B-lymphocyte (CD19+) and total lymphocyte (CD45+) counts, and IgG, IgM and IgA levels were measured at the beginning, at the 5th and 10th days of TPN. The immunological changes were compared with ANOVA test.
Results: The mean levels of IgG, IgM and IgA before TPN were 915·50 mg/dl, 107·15 mg/dl and 201·05 mg/dl, respectively. The mean initial counts of CD3+, CD19+ and CD45+ were 57·96 10^9/l, 34·96 10^9/l and 88·94 10^9/l, respectively. In the 5th day of TPN, the mean levels were measured as IgG 985·91 mg/dl, IgM 106·10 mg/dl, IgA 207·05 mg/dl, CD3+ 58·63 10^9/l, CD19+ 24·52 10^9/l and CD45+ 87·95 10^9/l. In the 10th day of TPN, the mean levels were measured as IgG 1102·8 mg/dl, IgM 128·90 mg/dl, IgA 209·22 mg/dl, CD3+ 66·82 10^9/l, CD19+ 28·96 10^9/l and CD45+ 87·51 10^9/l. There was an insignificant increase of IgG, IgA, IgM and CD3+ levels and an insignificant decrease of CD19+ level at the end of TPN when compared to the beginning of TPN (P>0·05), while there was no change in the levels of CD45+.
Conclusions: Contrary to conventional knowledge, TPN does not affect the immunological parameters negatively apart from a decrease in the levels of CD19+.

Malignant peritoneal mesothelioma following abdominal radiotherapy

A. Amin*, C. Mason** and P. Rowe*** **University Department of Surgery, Royal Free Hospital School of Medicine, London; **Department of Histopathology, ***Department of General Surgery, Eastbourne District General Hospital, Kings Drive, U.K.*

Malignant peritoneal mesothelioma MPM is a rare aggressive and highly malignant neoplasm. It is usually derived from the mesothelial lining of the peritoneal cavity and well documented to follow a long period of exposure to asbestos. It was also found to happen after radiation exposure. Previous reported cases of MPM classical presentation were four cases of malignant mesothelioma following treatment of Hodgkin's disease with radiotherapy.

Here we add two cases of primary malignant mesothelioma occurring many years after treating testicular neoplasm with abdominal radiotherapy and without any known history or clinical evidence of previous exposure to asbestos. Both patients were men fifty-five and sixty-four years old. Abdominal malignant mesothelioma had followed abdominal radiotherapy, which was given for testicular tumours (17–35) years before presentation. To establish the final diagnosis after excluding the other possibilities, malignant mesothelioma it is essential to remember as a possible cause of such rare abdominal lesion. Although our methods of obtaining tissue samples for histological confirmation were the explorative laparotomy. CT scan guided multiple fine needle aspirations could be a useful tool to achieve the same goal. Further staining of the tumour specimens immunohistochemically in addition to the haematoxylin-eosin staining was also done for additional confirmation. Tumour cells positively for CA125, epithelial membrane antigen and negativity for CEA are characteristic of malignant mesothelioma. All these variety of investigation are required to refute the possible peritoneal metastasis from a primary gastrointestinal adenocarcinomas.

In conclusion MPM may occur after long period of previous radiotherapy and may need to be considered in the list of possible diagnosis of peritoneal malignancy.

A prospective, randomized trial of early enteral feeding after resection for colorectal cancer

C. Beati, G. Samori, M.G. Gentile, E. Corradi, L. Gastaldo, M.A. Confalonieri and U. Pene *Department of Surgery 'M. Donati', San Carlo Hospital, Via Pio Secondo 3, 20153 Milan, Italy*

The purpose of the study was to determine whether early postoperative enteral feeding decreased mortality and morbidity in patients with colorectal cancer. Between January 1996 to September 1997, 65 patients with a resectable colorectal cancer were randomized to enteral feeding via jejunostomy tube (EEF) or control (CNTL). There were 41 male and 24 female with an overall mean age of 69·4 years. The table shows the site of colorectal cancer.

Site	EEF (No. of patients)	CNTL (No. of patients)
Right colon	8 (25·8%)	8 (23·5%)
Transverse colon	2 (6·5%)	2 (5·8%)
Left colon	13 (41·9%)	15 (44·1%)
Rectum	8 (25·8%)	9 (26·6%)
Total (65 patients)	31	34

Tube feeding was begun on the first postoperative day and advanced to a goal of 25 Kcal/kg per day. The CNTL were given intravenous crystalloid solutions. Patient preoperative status by nutrition risk index (NRI) and operative factors were similar between the groups. The results in terms of postoperative incidence of mortality and morbidity, and NRI decrease (from low-medium risk group to high risk group) between the groups were analysed by chi square test.

One patient in the EEF group had the jejunostomy tube dislocated in the abdomen cavity, required reoperation and was excluded from the study. The table shows the incidence of postoperative complication.

Complications	EEF	CNTL
Death	2 (6·4%)	2 (5·8%)
Sepsis	4 (12·9%)	6 (17·6%)
Nausea	6 (19·3%)	3 (8·8%)
Diarrhoea	1 (3·2%)	0

There was no significant difference in number of postoperative complications between the groups. There was no significant difference in postoperative NRI decrease between the groups (EEF vs CNTL 5/16 & vs 4/14 P=n.s.).

Early enteral feeding via jejunostomy was not beneficial in the postoperative treatment of colorectal resected cancer.

Learn operative surgery on a computer first

M.H. Edwards and P.J. Trigwell *Department of Surgery, Friarage Hospital, Northallerton, North Yorkshire, U.K.*

As an educational ideal, the surgical trainee should be so well instructed that he or she will be an expert in an operation before performing it for the first time. Traditional methods of surgical training fall short of this ideal, concentrating on the principles of the operation supported by learning on the job. This paper aims to demonstrate how training in operative surgery can move from apprenticeship towards preoperative expertise using computer based learning.

Two of our CD-ROMs, on Laparoscopic Cholecystectomy and Basic Surgical Skills, are the basis of the paper. We can demonstrate live at the Congress, given computer projection facilities, the many aspects of this work.

We have developed a new surgical language to allow virtually unlimited operative text in an accessible form for the trainee.

Multimedia features include the written word, diagrams, photographs, animations, video runs and a choice of voice to suit national preferences.

Interactive features include learning ability profiling; aptitude testing;

text annotation; customizing of equipment, materials, patient information, and nursing care plans; control of videos; dissection simulators; surgical decision simulators; drug dose calculators; surgical skidpans to let trainees test materials to destruction; speed and accuracy trials; and testing of trainees, with progress advice. A validation study is in progress.

We suggest that this type of computer based learning is an important and fast-developing method of making trainees competent before they start operating on patients.

New classification for ultrasonic carotid plaque morphology

T. Elatrozy, M. Griffin, S.A. Jmor, H. Elmorsy and A.N.N. Nicolaides *St. Mary's Hospital, QEQM Wing, Academic Vascular Surgery, London, U.K.*

Aim: To provide new operator independent classification of ultrasonic carotid plaque morphology.

Methods: 100 plaques (32 symptomatic, 68 asymptomatic; producing more than 50 per cent stenosis) were randomly selected. B-mode images were transferred to computer. Image standardization was performed so that adventitia and blood would have a grey value of 190 and 0 respectively (grey scale 0 = black; 255 = white). Plaques were outlined and the histogram of grey levels of the pixels was obtained. The median value of the grey scale level of pixels (GSM) was taken as a measure of overall echolucency (GSM <40 = echolucent; GSM >40 == echogenic). Kurtosis of the histogram was taken as an index of overall heterogeneity (<3 = heterogeneous and >3 = homogenous).

Results: A high incidence of symptomatic plaques (13/19; 41 per cent) was associated with a GSM <40 and a leptokurtosis (>3), compared to an incidence of 25 per cent (8/24; P=0·002 wilcoxon test). A GSM >40 and platykurtosis were associated with 33 per cent incidence of symptomatic plaques. The mean diameter stenosis was not significantly different among the three different groups (P=0·2, Wilcoxon test). Echolucent and homogenous texture are more likely to be associated with hemispheric symptoms.

Conclusion: Computer assisted methods identified a subgroup of patients at higher risk. This should be tested in future prospective CEA trials with stroke as an end point.

Vacuum sealing: a new and promising regimen in the therapy of radiation ulcers

L. Kovacs, M. Klöppel, M. Geishauser, S. Schmiedl and E. Biemer *Division of Plastic and Reconstructive Surgery, Klinikum rechts der Isar, University of Technology Munich, Ismaninger Str. 22, 81675 Munich, Germany*

Treatment of chronic radiation ulcers of any localization represents still a major challenge in surgery. These lesions develop on the basis of vascular malperfusion and chronic infection. Surgical intervention requires wound coverage by local flaps well described in the literature. Preoperative wound conditioning however is still a problem.

Established conservative methods of wound preconditioning are primary excision of the ulcers including bony lesions and induction of granulation by different means. The major concern about this strategy however is the cost intensity due to the duration of the treatment and costs for wound dressings, potential drugs etc.

Here we present an innovative wound dressing technique as an alternative treatment for radiation ulcers.

The treatment includes the following regimen. After wound excision and subsequent placement of polyvinylalcoholic (PVA) sponges wounds are continuously drained by draining tubes inserted into the sponge matrix. Next, the lesions are vacuum sealed by transparent vapour-permeable polyurethane foils. Finally, standard vacuum drainage containers, loaded with up to 80 kPa subatmospheric pressure, are connected to the tubes. Wound dressings have to be changed only every 7 days.

In this paper the advantages of wound dressing based on vacuum sealing in preoperative wound conditioning of radiation ulcers will be demonstrated by case reports.

The advantages of the specified technique are: 1) Reduction of the time required to clean the wound and earlier formation of granulation tissue by subatmospheric pressure thus enabling earlier operation. 2) Improved hygiene since the system represents a so-called closed system. 3) Reduction in material and personal costs.

In conclusion we consider vacuum sealing in the management of chronic radiation ulcers as an excellent alternative in wound preconditioning.

Hospital management, the surgeon as 'economist'

E. Rembs, K.-H. Bauer and V. Zumtobel *Chirurgische Klinik der Ruhr-Universität St. Josef-Hospital, Gudrunstr. 56, 44791 Bochum, Germany*

Considering the legal conditions there is no question that with the Health Structure Act (GSG) changes in hospital infrastructure have to be made by the surgeon and the administration cojointly. Contracts between hospitals and health insurances are covering costs for inpatient and outpatient surgical treatment. New forms of payment fee, either for case (Fallpauschale) or for service (Sonderentgelt) and a fixed budget for the hospital by the health insurances have been introduced.

Based on the establishment of an efficient computer software (Medwork) and hardware equipment (network with 25 single user workstations) all data for medical treatment in the surgical department are collected. The conversion of diagnoses and therapies to ICD-10/ICPM numbers is possible. By analysing the data and statistical evaluation 'controlling' is a major task for the physician in order for hospital decisions, cost containment and the use of cost effectiveness analysis.

Economical aspects and quality control of medical services, hospital budgets and finally planning capacity for hospital care are the new challenges for the surgeon.

From our experience an efficient budget control needs a complete and correct data recording – employing an efficient software – as well as strict medical control of profits along with continuous communication between the surgeons themselves and with the administration.

Cellular activity in human peritoneum after laparoscopic and conventional operations and in peritonitis

W. Sendt, R. Amberg*, K. Reinshagen, U. Schöffel, B.U. v Specht and E.H. Farthmann *Department of Surgery, University of Freiburg, Hugstetter Str. 55, 79106 Freiburg, Germany, *Institute of Forensic Medicine, Universit of Basel, Basel, Switzerland*

Aim of the study: The peritoneal trauma is reflected by an ill-defined influence on the patient's homeostasis. We therefore investigated immunohistochemically the local peritoneal response to different surgical procedures and peritonitis.

Materials and methods: In 10 patients, with laparoscopic or conventional cholecystectomy, peritoneal specimens were taken from the incision or parietal resection margins at the beginning and at the end of the intervention. In nine patients with diffuse peritonitis specimens were taken at the beginning of the intervention. Monocyte/-macrophage activity was assessed immunohistochemically using the antibody clone HAM 56 for local macrophages and antibodies against macrophages inhibiting factor (MIF)-related proteins 8 and 14 (MRP 8 and 14). Antibacterial protein (Defensin 3) reflected the activation of granulocytes. Cellular expression of interleukin 1 (IL-1), interleukin 6 (IL-6) and intercellular adhesion molecule-1 (ICAM-1) was additionally measured. All examinations were performed in paraffin sections using the Avitin-Biotin-Complex-technique.

Summary of results: Cellular activation (MRP 8 and 14, Defensin 3) as well as expression of adhesion molecules (ICAM-1) were increased in patients with either laparoscopic or conventional cholecystectomy. In peritonitis the expression of MRP 8 and 14 showed a focally increased interstitial staining whereas HAM 56 showed a relatively slight increase. The IL-1 expression in these patients was only discrete and in some cases not detectable.

Conclusions: The immunohistochemical evaluation of the local cellular response may provide objective criteria for the grading of the peritoneal trauma. Peritoneal response to laparoscopic or conventional cholecystectomy showed a comparable activation pattern. In peritonitis the peritoneal inflammatory reaction is relatively uniform. The surprisingly low expression of IL-1 may reflect downregulation after supposed early increase during the course of peritonitis.

Results after surgical treatment for pelvic floor disease in adult patients

F. Berrevoet, P. Pattyn, C. De Cock, P. Decroock, U.J. Hesse and B. de Hemptinne *Department of Surgery, University Hospital, De Pintelaan 185, 9000 Gent, Belgium*

To date no specific single ideal surgical treatment has been identified for pelvic floor disease including rectal prolapse, rectocoele, cystocoele, vault prolapse or a combination. The pathophysiology and controversies surrounding continence and constipation remain topics of debate. The present study summarizes our single center experience according to functional improvement after surgery.

Patients and methods: From February 1993 till November 1996 16 patients (1M, 15F) were treated for pelvic floor disease in our department, ranging in age from 34 to 75 years (mean 59 years). Initial disease was rectal prolapse in six patients, two in combination with rectal ulcers by intussusception, two patients with both rectocoele and prolapse, three patients with rectocoele, four with recto- and cystocoele and one patient with vault prolapse.

A detailed history was obtained from each patient both pre- and postoperatively, including functional symptoms as rectal dyschezia, faecal and urinary incontinence, anal manometry, constipation and recurrent prolapse. Surgical treatment consisted of rectopexy in six patients, in three combined with partial sigmoidectomy and 10 patients had a posterior colporaphy. Defecography and anal manometry was performed in all patients. Postoperative follow-up was 32 months (range 12–50 months).

Results: During follow-up none of the patients developed a recurrence of complete prolapse of rectum or vault. Faecal incontinence was still present in one of six patients (16·6 per cent) who had complaints before surgery. Rectal dyschezia is present in two patients of 10 (20 per cent), urinary incontinence was absent in all patients after treatment (0/4). Constipation was pre-operatively seen in 15 of 16 patients, while after surgery no problems occurred in all patients. Six patients however had to use medication. Post-operatively no insufficiency of the pelvic floor musculature was seen with anal manometry.

Conclusion: The present study demonstrated that the risk of developing recurrence of the symptoms after surgical treatment is rather small. Surgery therefore is a valid option in the treatment of these conditions with only minimal mid-term morbidity.

Giant retroperitoneal tumour: myxoid liposarcoma

F.J. Del Rio Lafuente and F. Del Rio Marco *Department of General Surgery, 'Miguel Servet' Hospital, Paseo Isabel la Católica 1–3, Zaragoza 50009, Spain*

Introduction: Retroperitoneal tumours emerge from connective, nervous and embryonal structures situated in the retroperitoneal space and separate from the kidney, the suprarenal glands and the large vessels.

Liposarcoma is an uncommon tumour of mesodermic origin. It presents an histologically heterogeneous structure with some differentiated lipomatous type regions and others constituted by lopoblasts (irregularly shaped cells).

These tumours have a slow development and frequently reach a large size, which makes compressive symptoms the condition's most common manifestation. Growth is primarily local with little tendency to metastasize.

Material and method: A case of giant retroperitoneal tumour is presented. The symptoms and investigations are as follows: abdominal ultrasonography demonstrated a solid and hyperechogenic, large abdominal mass occupying the pelvis and right hemiabdomen. Abdominal CAT: heterogeneous retroperitoneal mass of a predominantly fatty nature causing migration of abdominal viscera. IV urogram: both kidneys shifted to the left mimicking cross-over ectopia. Echoguided puncture biopsy: cytology compatible with sarcoma.

Results: Surgery was done by block removal of the tumour. Dimensions of surgical piece removed were 40×40×14 cm, weight 13 730 kg.

Pathoanatomical diagnosis was a well differentiated liposarcoma with areas of myxoid liposarcoma.

Conclusions: Surgical resection of the tumour in a block is the choice treatment. Chemotherapy whether alone or associated with radiotherapy does not appear to obtain good results due to the low radiosensitivity of these conditions.

Effects of thyroid hormones on stress ulcer: an experimental study

A. Koyuncu, S. Koçak, S. Aydıntuğ, E. Kuterdem and S. Özbas *Ankara University Medical School, Department of Surgery, 06100 Sıhhıye, Ankara, Turkey*

Aim of the study: Some non-thyroid diseases which cause stress, influence the serum thyroid hormone levels. It has been shown that there is a correlation between the severity of the gastric mucosal erosions and the decrease in thyroid hormone levels, in stress. We evaluated the possible protective effect of thyroid hormones on gastric mucosal lesions in a rat stress model.

Materials and methods: Stress (24 hours of hunger and six hours of stretch in supine position) was applied to five groups of rats, each of which contains 15 rats. Group I was the control group. Thyroxine (T4) was injected intramuscularly to the rats in the group II and III, and Triiodoythyronin (T3) was given intraperitoneally to the group IV and V. The thyroid hormone injections were made before the stress in groups II and IV, and during the stress in groups III and V.

After death blood samples were taken for thyroid hormone levels. Gastric pH of each rat was measured, gastric mucosal lesions were evaluated and histopathological examinations were performed.

Summary of results: It was found that gastric mucosal lesions were decreased in length and depth by thyroid hormones in all of the four treatment groups compared with the control group ($P<0 \cdot 001$). However, gastric pH levels were about the same with the control group. T3 levels were found to be elevated in group II, in which T4 was given during stress.

Conclusions: We conclude that thyroid hormones protect the gastric mucosa in both prophylactic and therapeutic usage. This result indirectly reveals that there becomes no decrease in 5'-deiodinase enzyme activity in stress.

Sugiura procedure in the treatment of bleeding esophageal varices

U. Lepner, T. Vaasna, E. Rebane and V. Tamm *Surgical Clinic of Tartu University, 8 Puusepa str. EE2400, Tartu, Estonia*

Aim of the study: The aim of this study is to report our results and to make an attempt to define the possible role of the Sugiura procedure in the treatment of variceal bleeding.

Materials and methods: From January 1979 to December 1997, 39 patients with portal hypertension and acute variceal bleeding (17 patients) or with previous variceal bleeding (23 patients) underwent a Sugiura procedure. Operations were performed in two stages. When performed in an emergency situation (17 patients) the thoracic operation was performed first. In elective cases (23 patients) the more laborious and risky abdominal operation was preferred. The second stage, either abdominal or thoracic procedure, respectively was performed 4 weeks to 6 months later. A complete two-stage operation was performed in 16 patients. 23 patients did not undergo the second stage because of early postoperative death, deterioration of condition or refusal. There were 17 men and 22 women, aged 41·7±18·3 years (range 8–71 years). 27 patients (69 per cent) had cirrhosis. Three patients had noncirrhotic intrahepatic portal hypertension and nine patients had extrahepatic portal or splenic vein thrombosis. According to the Child–Turcotte classification of hepatic function there were 23 Child class A, 13 Child class B and 3 Child class C patients.

Summary of results: Overall operative mortality was 7·4 per cent (four out of 54 operations), mortality cases in emergency situation 17·6 per cent (three out of 17 operations) and in elective cases 2·7 per cent (three out

of 38 operations) Variceal rebleeding occurred in four survivors (11·4 per cent) at an average follow up of 6·1±4·3 years. Survival rate was 84·6 per cent at 1 year, 71·8 per cent at 5 years and 64·1 per cent at 10 years.
Conclusions: Sugiura operation carries low operative risk in an elective situation and results in an effective prevention of recurrent variceal bleeding.

Giant haemangiopericytoma

L. Rodríguez, J. Lesaga, M. Piris, J. Vera, A. Mira and
E. Bengoechea *Hospital Virgen de la Salud, Avenida de Barber,
30 Toledo 45004, Spain*

Haemangiopericytoma is an unusual vascular tumour, that arises from the pericapillary pericyte cells of Zimmermann. It was described by Stout and Murray in 1942; and 25 per cent arise from the retroperitoneum and pelvic cavity.

A 46 year old male, came to the emergency room because of pain and oedema in the left lower extremity. On physical examination the abdomen appeared globular, and had one big intraabdominal mass. Signs of deep venous thrombosis were present. Blood studies were normal (include tumoral markers). We performed several X-rays examination: plain abdominal, pylography, ultrasonography, CT-scan, angiography, duplex-scan. We founded a soft tissue mass in the mesentery and pelvic cavity, with displacement of the bowel, bladder and the ureters The mass had cystic low attenuation zones and enhancement of solid areas with calcifications.

On the laparotomy we founded a giant and hypervascular mass, located in the mesosigmoid and pelvic cavity. The patient underwent complete excision of the tumour with sigmoidectomy and ureteral liberation End to end colorectal anastomosis was carried out. In the postoperative period the patient developed a urinary fistula, which was treated conservatively with drainage.

Pathology revealed a large tumour (30×25×22 cm), pseudoencapsulated and weighing 3560 g Microscopically the tumour showed small cells, with oval nuclei. The vascular channels usually formed a continuous ramifying vascular network or a 'staghorn' configuration. Few mitotic figures (One per 10 high power fields). Immunohistochemical stain for vimentin and CD 34 were positive The diagnosis was a 'low grade malignant hemangiopericytoma' The cytology of peritoneal fluid was negative
Conclusions: Big size and weight of the tumour The first symptom was a venous thrombosis Intratumoral calcification (less than 1 per cent of the cases). Sigmoid and ureters encapsulated.

Follow-up later one year is normal.

The mechanism of leg ulcer healing under the influence of the He-Ne laser irradiation

J. Wasiak, U. Mikulska and L. Wolf *Department of General
and Transplant Surg. Kopcińskiego 22, 90–153 Łódź, Poland*

Planimetric assessment of the healing process of diabetic leg ulcers proved that granulation and epithelization rate in diabetic neuropathy is 2–8 times more effective than in ischaemic ulcers (venous, arterial) This study was performed to show a mechanism of stimulation by He-Ne laser irradiation on cells of granulation tissue of these ulcers Activity of superoxydysmutase (SOD) was assessed in homogenated granulation tissue removed from ulcers due to overgrowth – before and after irradiation Simultaneously concentration of linked diens and malonic dialdehyd (MDA) as products of lipid's peroxydation was measured. He-Ne laser irradiation causes significantly higher activity of SOD and at the 4th day of therapy also significantly decreased concentration of linked diens and MDA. Stimulated by He-Ne lasers superoxydysmutase reduced peroxydation of intracellular lipids in human granulation tissue. This study is the first in human pathology

Biliary complications after orthotopic liver transplantation: influence of graft shipment?

F. Berrevoet, U.J. Hesse, R. Troisi, I. Kerremans, E. Daeter, P. Pattyn and B. de Hemptinne *Department of Surgery, University Hospital, De Pintelaan 185, 9000 Gent, Belgium*

Stenoses at the anastomotic site, biliary obstruction, leakage and infections occur both in the immediate postoperative phase and even several years after orthotopic liver transplantation (OLT) and are frequently the cause of reoperation. The influence of organ preservation, including flushing of the bile duct, by a team of surgeons other than transplant surgeons is investigated in this study, together with the etiology of the biliary complications itself.

Patients and methods: From May 1991 till May 1997 210 OLT were performed in our institution in 167 adults and 43 children. 180 primary transplants were included in this study, 27 retransplantations and three patients included were second retransplants. Preoperatively donor status, shipment of the graft, flushing of bile ducts at the time of preservation and recipient age were studied, while after transplantation type of biliary anastomosis, postoperative biliary complications and patient and graft survival were observed. For statistical analysis Kaplan Maier-method was used.

Results: 70 transplantations were performed using a shipped donor liver, in four cases (5·7 per cent) the bile duct was not flushed at the time of preservation. Liver disease without involvement of the extrahepatic biliary tract was diagnosed in 186 transplants (88·6 per cent) (58 shipped, 128 non-shipped), while 24 patients (11.4 per cent) had involvement of the extrahepatic biliary tract (12 shipped, 12 non-shipped). 148 patients had an end-to-end anastomosis of the common bile ducts, 58 patients had a choledochojejunostomy and in four patients a choledochocystostomy was performed. A **T**-tube was placed in 83 patients (39·5 per cent). Postoperative biliary complications were seen in 21 (10 per cent) patients (nine shipped (12·8 per cent), 12 non shipped (8·6 per cent, P=n.s.) while one patient of four (25 per cent) where the bile duct was not flushed in the shipped group had biliary leakage (P=0·02). 10 patients had peritonitis because of biliary leakage (4·3 per cent), two patients with peritonitis because of a biliary fistula and perforation of the Roux-en-**Y** respectively. Seven patients (three children, four adults) had biliary obstruction, due to stenosis of the anastomosis (n=3), necrosis of the bile ducts (n=1), haemobilia (n=1), choledocholithiasis (n=1) and recurrent auto-immune hepatitis (n=1). One patient was reoperated because of an obstructed **T**-tube and one because of biliary sludge. No mortality because of biliary complications occurred with graft survival after 3, 6 and 12 months of 86·6 per cent, 79·4 per cent and 70·4 per cent respectively. Patient survival at the same time was 94·3 per cent, 91·2 per cent and 87·9 per cent.

Conclusion: Liver transplantation has reached a high technical standard, the biliary reconstruction frequently may complicate the postoperative recovery. Although the reported incidence for biliary complications is up to 20 per cent in literature, no increased mortality in these patients can be seen. Shipping of liver grafts may cause these complications in particular when flushing of the bile duct is not adequately performed.

Vascular complications (VCs) after renal transplantation

L. Cierpka, G. Budziński, R. Król and S. Kuśmierski *1st Department of General Surgery, Silesian Medical Academy, ul. Francuska 20–24, 40–027 Katowice, Poland*

VCs are the reason for 16·5 per cent of deaths and 12·5 per cent of haemodialyses because of delayed graft function after renal transplantations. VCs can be divided into arterial venous, connected with lymph leak as well as early and late.

The analysis of 339 patients with grafts harvested from cadaveric donors operated on in our Department from 1990 to 1997 was performed. Early arterial complications (up to three weeks after surgical procedure) – such as bleeding from: arterial anostomosis, small vessels of the kidney hilium and retroperitoneal space or ruptured kidney during rejection, occurred in 46 cases (13·6 per cent), and graft or lower limb ischaemia occurred in 18 (5·3 per cent). Early venous complications such as renal or iliac vein thrombosis occurred in three cases (0·9 per cent).

There were 65 (19·2 per cent) late arterial complications including six arterial anostomosis strictures giving signs of hypertension, five ischaemic ureteric strictures and 54 cases (15·9 per cent) of late renal artery and vein thrombosis caused by chronic rejection, three cases of impaired drainage of lymph from the graft area after surgical procedure were included as VCs as well.

VCs were the reason for recipient death in six cases and of graft loss in 54 (15·9 per cent). Most of the VCs are connected with the processes of acute rejection (graft rupture) and chronic rejection (arterial and venous thrombosis). Late graft ischemia is caused by atherosclerosis or endothelial proliferation in the site of anastomosis.

Liver transplantation in patients with cirrhosis and primary cellular hepatocarcinoma. How useful is the tumour staging?

L. Herrera, E. Martino, J. Castillo, F. Hernanz, J. Crespo, F. Casafont, D. Casanova and M. Gómez Fleitas *Hospital Universitario 'Marqués de Valdecilla', Santander, Cantabria, Spain*

Background: Because of the effectiveness of liver transplantation, some aspects of the treatment of patients with liver cirrhosis have become challenging topics. One of these is the staging accuracy for the hepatocellular carcinoma (HCC) in the cirrhotic liver, in order to provide an adequate indication for the definitive treatment.

Aim of the study: To evaluate the diagnostic accuracy of HCC in cirrhosis using the clinical methods nowadays available.

Patients and methods: In our Institution, from November 1990 to January 1998, 202 orthotopic liver transplantations (OLT) with a piggyback modified technique were performed in 183 patients with end stage liver disorders. Diagnoses was made preoperatively by biological probes (alpha-fetoprotein), image methods as ultrasonography, magnetic resonance imaging, computerized tomography (CT), CT portography, lipiodol CT and hepatic angiography and also percutaneous needle biopsies of the suspicious images.

Results: In 33 patients, HCC diagnoses was made (32 with liver cirrhosis). The other 150 were considered to be free of HCC. In four of them, also with liver cirrhosis, HCC was found postoperatively (false negative). Three of these were incidental tumours (1 per cent) and the other one was a suspicious image with a negative preoperative citology. 11 of the 33 preoperative HCC with liver cirrhosis (33·3 per cent) showed no postoperative malignancy (false positive). pTNM classification for the patients with HCC (26) is shown in the table.

Year survival	Stage I (n=1)	Stage II (n=16*)	Stage III (n=5)	Stage IV A (n=4)	Global (n=26*)
1	0·0	0·81	0·4	0·75	0·69
2	0·0	0·75	0·4	0·75	0·65
3	0·0	0·69	0·4	0·75	0·61
4	0·0	0·69	0·4	0·75	0·61
5	0·0	0·69	0·4	0·75	0·61

*One with no liver cirrhosis

Okuda preoperation situation of HCC patients was as follows: 10 (40 per cent) stage I, 11 (44 per cent) stage II and 4 (16 per cent) stage III. When comparing the survival of the HCC and non-HCC groups by Kaplan-Meier method, the results were similar (0·615 for HCC and 0·696 for non HCC) with a follow up of 77 and 87 months, respectively). In summary, HCC incidence in our series was 0·18, with a 0·97 and 0·67 of specificity and sensitivity for HCC diagnoses respectively.

Conclusions: In our institution, as in many others, OLT has proved to be a useful alternative in the treatment of cirrhotic patients with HCC. Overall sensitivity for the HCC preoperative diagnoses is very poor in this group of patients. So, we think that, in the absence of more accurate diagnostic procedures, the staging efforts in cirrhotic patients with HCC who are candidates for OLT, are nowadays unhelpful.

Improved hemodynamics with temporary porto-caval shunt in orthotopic liver transplantation

U.J. Hesse, F. Berrevoet, R. Troisi, E. Mortier, P. Pattyn, M. Ongenae, J. Decruyenaere and B. de Hemptinne *Department of Surgery, University Hospital, De Pintelaan 185, 9000 Gent, Belgium*

There are several theoretical and practical aspects to preserve the recipient vena cava during hepatectomy for orthotopic liver transplantation. However in patients with insufficient collateral circulation, excessive haemorrhage and major portal hypertension a veno-venous bypass or temporary porto-caval shunt alternatively can be used in order to maintain haemodynamic stability, adequate renal perfusion pressure and an undistended intestine to facilitate graft implantation. In the following study the experience with latero-lateral cavo-cavostomy for hepato-venous reconstruction is reviewed with and without the use of veno-venous bypass or temporary port-caval shunt.

Patients and methods: A total of 54 liver transplantations were analysed. In 38 transplantations a latero-lateral cavo-caval anastomosis was performed (Group I). In Group II (n=8) the same technique was performed, using a veno-venous bypass and in Group III (n=8) a temporary portal caval shunt was constructed. Patients were comparable with regards to age, Child Pugh, urgent/elective, preoperative mean creatinine, cardiac index, donor age, cold ischemia time and operating time.

Results: Mean arterial pressure (mmHg): Group I 128±34; Group II 114±28; Group III 108·6±32. Cardiac index decrease during the operation was 2·3±1·9, 1·5±0·6 and 1·2±1·0 respectively (P=0·05). The peroperative blood loss packed cells was 16·4±15·8 vs 4·5±10·5 vs 1·2±2·3 (P=0·004) and for fresh frozen plasma it was 19·0±14·7 vs 8·0±6·4 vs 3·7±4·0 (P=0·002). Course on ICU (days), liver function tests, renal function and the need for reoperation because of bleeding were not statistically significant different between the groups. One year patient survival was 82·7 per cent vs 69·4 per cent vs 85·7 per cent.

Conclusion: Despite preservation of the caval flow, the additional use of a temporary porto-caval shunt or a veno-venous bypass was advantageous with regards to operoperative haemorrhage as measured in loss of packed cells and fresh frozen plasma. There was no difference between the group of veno-venous bypass and porto-caval shunt. Cardiac index decreases less with the temporary porto-caval shunt and it appears to be suitable to avoid excessive portal hypertension and associated haemorrhage and potentially facilitates the implantation of the graft.

Ischaemic injury in donor hearts: immunohistochemical identification of complement membrane attack complex in the presence of normal histology

J.A.J. Hyde, S.R. Rooney, M.P.I. Pitt, I.C. Wilson, A. Howie and R.S. Bonser *Department of Cardiac Surgery, Queen Elizabeth Hospital, Birmingham*

Aim: Primary graft failure (PGF) is responsible for 15–20 per cent of early deaths following heart transplantation. Myocardial injury may occur as a consequence of catecholamine 'storm' at brainstem death, inadequate myocardial protection, or delayed reperfusion. Our aim was to investigate a novel technique for identification of myocardial ischaemic injury, with potential application to evaluation of donor hearts.

Methods: In order to assess myocardial injury prior to implantation, we investigated myocardial biopsies obtained at retrieval in 33 donor hearts by routine haemotoxylin-eosin histology, and immuno-histochemical identification of the C5b-9 complement membrane attack complex (MAC), a validated early marker of ischaemia*. Donor and recipient records were reviewed to establish inotrope requirement and outcome. Donor hearts were assessed by inspection and haemodynamic evaluation. Acceptance criteria included normal gross morphology, filling pressures <12 mmHg, and cardiac index >2·4 L/min/m^2 on minimal inotropic support.

Results: All donors had normal ECG patterns. All conventional histology was normal, but six biopsies (18 per cent) stained C9 positive. Of these, one heart was not implanted due to haemodynamic instability of the donor during retrieval, and two patients (40 per cent of implants) died of PGF. Two further patients (40 per cent of implants) in the C9 positive group required prolonged postoperative inotropic support. In the C9 negative group, 2/27 (7·4 per cent) died of PGF, compared to an overall unit 30 day survival of 90 per cent.

Conclusion: This pilot study identifies pre-retrieval myocardial ischaemic injury as an important contributor to recipient outcome, and suggests that improved techniques to evaluate donor hearts may reduce the incidence of primary graft dysfunction.

*J. Doran, A. Howie, J. Townend and R. Bonser. Detection of myocardial infarction by immuno-histochemical staining for C9 on formalin fixed, paraffin wax embedded section. *J Clin Pathol* 1996; 49: 34–7.

Use of sirolimus overcomes risk factor of African–American race

H. Podder, J. Podbielski, S.M. Katz, C.T. Van Buren and B.D. Kahan *Division of Immunology and Organ Transplantation, University of Texas Medical School, Houston, 6431 Fannin, Suite 6.240, Houston, Texas 77030*

Aim of study: Despite successful transplant operations, African–American renal transplant recipients experience a higher degree of graft loss due to an increased incidence of noncompliance, hypertension, mismatches for racially associated antigens, and resistance to immunosuppressants. 10-year results of renal transplantation, wherein 89 per cent were primary transplants and 11 per cent were re-transplants, document a greater efficacy of cyclosporine (CsA) over azathioprine (AZA) on patient (85 per cent vs. 80 per cent, P= 0·04) and graft survival. At 1, 2, 3, 4, 5, and 6 years, CsA provides significantly better graft survival than AZA-based regimens; however, by 10 years, the CsA results match with those of AZA. Although CsA (Sandimmune)-based therapy has limited impact on long-term survival rates, the addition of sirolimus (SRL) to the CsA regimen may offset the adverse impact of African–American race on patient and graft survival.

Materials and methods: 58 patients were treated with varying doses of SRL in addition to CsA therapy. At one year, we examined patient and graft survival. Log rank statistic tests were used to determine graft and patient survival rates.

Summary of results:

1-Year Graft and Patient Survival for 58 SRL-Treated Patients

	n	Graft survival	Patient survival
Black	15	86·7%	100%
White	43	92·7%	95·2%

P=NS

Conclusions: Addition of SRL to a CsA-based regimen overcomes the higher rates of graft loss and death among African–American renal transplant recipients. Thus, SRL represents a significant new addition to the immunosuppressive armamentarium. New drug strategies for improving rates of acute rejection among African–American patients will need to be assessed in the future.

Isolated lung transplantation for end-stage lung disease

F. Venuta, E.A. Rendina, T. De Giacomo, G. Della Rocca, S. Quattrucci, C.D. Vizza, A.M. Ciccone, M. Moretti, E. Guarino, C. Ricci and G.F. Coloni *University of Rome 'La Sapienza', Policlinico Umberto I. Dpt. of Thoracic Surgery, Anesthesiology, Pediatrics and Cardiology*

Since 1991 we have performed 37 isolated lung transplantations for end-stage pulmonary disease: 15 single (SLT) and 22 bilateral sequential (DLT) (1 bilateral lobar). Recipient diagnoses were: cystic fibrosis (13), chronic obstructive lung disease (11), pulmonary fibrosis (9), bronchiectasis (4). Two patients had undergone lung transplantation while on ventilatory support for respiratory failure (SLT for pulmonary fibrosis). Three patients required cardiopulmonary by-pass (2 SLT and 1 DLT) which was associated with increased transfusion requirement. In 13 cases the donor lungs were reduced with multiple GIA staplers to fit the size of the recipient. During SLT the bronchial anastomosis was protected with an intercostal muscle pedicle while during DLT we used only mediastinal fat tissue. Five patients died after SLT (33·3 per cent) (1 to 42 days). After SLT the remaining native lung was the site of early (pneumonia, overinflation, retention of secretions with atelectasis, haemothorax) and late complications (recurrent pneumothorax, progressive overinflation, aspergillosis, nocardiosis) in seven patients (47 per cent). Three patients (17·6 per cent) died after DLT (oesophageal perforation: 1; heart failure: 1; primary graft failure: 1). One-year survival for SLT and DLT is 66·7 per cent and 82 per cent respectively. One patient has obliterative bronchiolitis controlled with increased immunosuppression six years after SLT. Three patients have a bronchial stenosis treated with laser resection and stenting. Cytomegalovirus infection has been seen frequently (nine cases) but has responded well to treatment with Gancioclovir. Other complications were sternal infection (2), wound infection (2), renal failure (3), bleeding requiring reoperation (3) and psicosis (3). Isolated lung transplantation can be performed with acceptable morbidity and mortality in properly selected patients with a variety of end-stage lung diseases. Improvement in lung function and quality of life can be achieved with both SLT and DLT; however, after SLT the native lung may be the site of onset of serious complications; for this reason we tend to increase the indications to DLT even for non-septic lung diseases.

Assessment of cardiac rejection by magnetic resonance imaging (MRI) and spectroscopy (MRS)

B.H. Walpoth, T. Carrel, B. Celik, M. Müller, B. Aeschbacher, T. Schaffner and U. Althaus *Cardiac Surgery, Cardiology, Radiology, MR-Unit, Pathology, University Hospital, Bern, Switzerland*

Objective: In experimental orthotopic cardiac transplantation magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS) and Echocardiography were compared as non invasive diagnostic tool for detection of cardiac rejection.

Methods: Six orthotopic cardiac transplantations were performed in the swine on cardiopulmonary bypass and immunosuppression (triple therapy) was tapered after 10 days to obtain increasing rejection. The following measurements were performed on a 1·5TGe Signa (double tuned flexi-coil, gradient echo cine and 2 D-CSI) and on an Acuson 128XP10 on postoperative day 1, 3, 10, 17, 24 and 31: MRI: cardiac function and LV-mass, MRS: 31 P MR-spectroscopy, Echocardiography (transthoracal) and Rejection grading (ISHLT/Texas).

Results:

1. MRI: LV function increased (EF=+17 per cent) and LV mass increased (+41 per cent) with time and increased rejection ($P<0{\cdot}05$).
2. MRS: A significant reduction of phosphocreatine to adenosine triphosphate (PCr/ATP) occurred when comparing pre- to postoperative exams (−17 per cent; $P<0{\cdot}01$).
3. Echocardiography: Wall thickness increased markedly postoperatively (+27 per cent intraventricular septum and +17 per cent left posterior wall) whereas per cent shortening (+6 per cent) and ejection fraction (+8·5 per cent) did not change significantly.
4. Pathology grading showed an increased rejection with time especially after tapering immunosuppression. At autopsy rejection was mild in 2, moderate in 1 and severe diffuse (ISHLT 3B/Texas 6–7) in 3 animals.

Conclusions: MR-imaging and spectroscopy seem to be a promising tool for non invasive assessment of rejection. A significant reduction of phosphocreatine to ATP occurred when cardiac rejection was present. Thus cardiac rejection may be detected non invasively by MR-imaging and spectroscopy in the animal.

Acute cholecystitis: different therapeutic attitudes in our service in the last 4 years (232 cases)

J. Ariceta, J.V. Ferrer, A. Calvo, L. Blazquez, F. Vicente, E. Balén, J. Herrera and J.M. Lera *General Surgery, Navarra Hospital, Irunlarrea 3, 31008, Pamplona, Spain*

Introduction: The commonly accepted approach in the treatment of acute cholecystitis is urgent cholecystectomy. Laporoscopy has renewed interest in the option of 'cooling' the inflammatory process, in order to subsequently carry out a programmed cholecystectomy through the technique mentioned. We present an analysis of the data collected on hospital stay and medico-surgical complications in both therapeutic options.

Material and methods: We studied 232 patients presenting as emergencies between January of 1994 and December of 1997 with diagnosis of acute cholecystitis. They were distributed in three groups: A) operated on in their first admission; B) patients with high risk for a general anesthesia, treated by percutaneous cholecystostomy; C) treated using 'cooling' of the process to be operated on in a second admission.

We analysed the simple and accumulated hospital stay, the index of medical and surgical complications and mortality with a 't-student' program.

Results: Acute cholecystitis: 232.

A group: 137, 35 with associated surgery.

B group: 16. New admission: 4, 2 new acute cholecystitis, 2 open cholecystectomy.

C group: 79. New admission: 41, 6 new acute cholecystitis, 12 open and 23 laparoscopic cholecystectomy.

	Patients	Mean age	Hospital stay	Accumulated stay by new cholecystitis	Accumulated stay by reentry for surgery	Medical complications	Infections	Deaths
A	137/232 (59·0%)	69·1	11	0	0	33/137 (24·0%)	14/137 (10·2%)	3/137 (2·1%)
B	16/232 (6·8%)	80·6	15·6	17·35	16·6 (open)	7/16 (43·7%)	4/16 (25%)	2/16 (12·5%)
C	79/232 (34·0%)	67·3	7·8	13·8	15·8 (open) 14·6 (lap)	17/79 (21·5%)	4/79 (5·0%)	2/79 (2·5%)

Conclusions: Urgent surgery seems the most suitable approach in acute cholecystitis to be a sure and effective procedure; the patient from a single admission, avoids the risk of recurrent pathology from cholelithiasis (new acute cholecystitis, biliary pancreatitis…), with shorter hospital stay, without an increase in morbidity or mortality, with the economic repercussion that this has furthermore for the health system.

Open cholecystectomy in the laparoscopic era: implications for surgical training

M.K. Barry, C.M. Gallagher, D.C. Grant, P. Connell, O. Traynor and J.M.P. Hyland *Department of Surgery, St. Vincent's Hospital, Elm Park, Dublin 4, Ireland*

Aim: The aim of this study was to review our experience of open cholecystectomy in the laparoscopic era.

Methods: Since July 1990 a total of 927 cholecystectomies have been performed in our unit. All patients who underwent open cholecystectomy were reviewed. These included 66 of 801 laparoscopic cholecystectomies converted to an open procedure (8·2 per cent) and 126 open cholecystectomies.

Results: Of the combined total of 192 patients treated by open cholecystectomy, there were 127 females and 65 males. 41 patients had elective open cholecystectomy during the transition year after the introduction of laparoscopic surgery. Thereafter the most common indications for open operation were, previous abdominal surgery (n=21), suspected malignancy (n=10) and empyema/mucocele (n=10). Indications for conversion in the 66 patients included anatomical uncertainty (n=42), empyema (n=11), bleeding (n=4) and technical problems (n=4). Two patients died post operatively (1 per cent). The overall complication rate was 23 per cent (n=44); cardiorespiratory (n=22), retained common bile duct stone (n=3), deep venous thrombosis (n=2), sub phrenic abscess (n=2), bile duct injury (n=2), wound infections (n=2), post op haemorrhage (n=2) and miscellaneous (n=9).

Conclusions: Even in the laparoscopic era open cholecystectomy is required in a percentage of patients, many of whom present with complicated biliary tract disease and associated morbidity. These patients require experienced surgical management which has major implications for surgical training.

Complications after surgical biliary-enteric drainage

M. Borrego Galán, P. Yunta, J. Del Pino, C. Herrera, J. Silvestre, S. Carceller, M. Meseguer and S. Sancho Fornos *Cirugía General Hospital Universitario 'La Fe', Av Campanar 21, 46009 Valencia, Spain*

Aim: The aim of this study is to analyse the complications after biliary-enteric drainage in the management of obstructive jaundice.

Material and methods: Between 1989 and 1996, 253 surgical drainage procedures were performed in our Department: 44 sphincterotomy (SP), 183 choledochoduodenostomy (CD) and 26 hepaticojejunostomy (HJ).

In the case of SP there were four acute pancreatitis (nine per cent) one of them caused death. Residual choledocholitiasis was evidenced in three cases of the 35 SP practiced because of choledocholitiasis (8·5 per cent).

Biliar stricture appeared in two cases (4·5 per cent). 183 patients underwent CD. The complications were: three acute cholangitis (1·6 per cent), 2 anastomosis strictures (1 per cent) and 4 external biliary fistulae (2·7 per cent) three of them after drainage for malignant obstructive jaundice.

Postoperative complications in the case of hepaticojejunostomy were: 1 stricture of the anastomosis (3·8 per cent) and two biliary strictures (7·6 per cent).

Conclusions: Our results suggest that complications after drainage techniques are unusual but early diagnosis is necessary to reduce morbidity and mortality rates.

Double blind randomized controlled trial of buccal suscard versus placebo in the prevention of endoscopic retrograde pancreatographic induced pancreatitis

E. Bromwich and P.R. Edwards *Department of Surgery, Countess of Chester Hospital NHS Trust, Liverpool Road, Chester, England*

Pancreatitis is the most common complication of Endoscopic Retrograde Cholangiopancreatography (ERCP) occurring in up to 30 per cent of patients. Previous studies have failed to show any benefit in the use of somatostatin or corticosteroids in decreasing its incidence. Sublingual glyceryl trinitrate relaxes the peri-ampullary sphincter muscle and may reduce pancreatic duct pressure thereby reducing the risk of ERCP induced pancreatitis.

186 patients were randomly allocated to receive either placebo (P) (n=96) or buccal suscard (BS) (n=90) 5 minutes pre-procedurally. At ERCP, sphincterotomy, stent insertion and stone extraction were undertaken as indicated. Six hours post-procedurally all patients were asked to quantify their pain and a serum amylase estimation was undertaken. Pancreatitis was defined as the presence of pain in conjunction with a serum amylase in excess of 1000 IU.

The overall cannulation rate was 92·5 per cent (172/186). There was no statistical difference in the cannulation rates between the two groups (P = 88/96 = 91·75 per cent) and (BS = 84/90 = 93·3 per cent).

Pancreatitis occurred in 17 patients in the P Group and seven patients in BS Group (P>0·05). The difference in proportions is 0·787 and the 95 per cent confidence intervals for the true difference is 0·699 to 0·875. Statistical analysis was by a Chi-squared test with Yates' correction.

Although buccal suscard has not been shown to significantly decrease ERCP induced pancreatitis the results do suggest that further work needs to be undertaken on this drug.

Serum CA19-9 and CEA: are they useful as early gallbladder cancer markers?

J. De Tomás, J. Carretero*, E. Alvarez* and M. Trinchet
*Department of Surgery, *Department of Pathology, U.G. Hospital Gregorio Marañón, Doctor Esquerdo 46, 28007 Madrid, Spain*

Aim: To assess the feasibility of serum carcinoembryonic antigen (CEA) and carbohydrate antigen (CA19-9) levels as early markers of chronic cholecystitis neoplastic degeneration related to gallstones. Benign conditions associated with a rise in serum CA19-9 levels would be identified.
Methods: A prospective study was undertaken of 75 consecutive operated patients of median age 71·8 (range 60–90) years due to symptomatic cholelithiasis. The study group was collected among subjects aged 60 years and over because of the late presentation of gallbladder cancer. There were 51 females and 24 males (ratio 2·1/1). One single surgeon and two pathologists performed the collection and histological study of the specimens, which were fixed in Carnoy and stained with hematoxylin and eosin. Serum CEA and CA19-9 levels were obtained on the day of operation.
Results: Of the 75 patients, 31 showed benign hepato-pancreato-bilary diseases associated with increasing CA19-9 serum levels: acute pancreatitis (12), obstructive jaundice (10), acute cholecystitis (6) and cirrhosis (3). However, only two patients showed a slight increase over normal serum CEA levels. The first one suffered an acute cholecystitis with an unsuspected gallbladder adenocarcinoma and miliary liver metastases (CEA: 7·2 ng.ml, CA19-9:83·5 u/ml); the other one had cirrhosis (CEA: 7·5 ng/ml, CA19-9:45·6 u/ml). Of the remaining 44 patients, the median serum markers levels among the different epithelial findings were: normal (n=21, CEA=2·5 ng/ml, CA19-9=15·8 u/ml) hyperplasia (n=12, CEA=2·1 ng/ml, CA19-9=12·5 u/ml), gastric metaplasia (n=10, CEA=4·9 ng/ml, CA19-9=9·9 u/ml), dysplasia (n=4, CEA=3·9 ng/ml, CA19-9=15·7 u/ml), intestinal metaplasia (n=3, CEA=5·5 ng/ml, CA19-9=11·3 u/ml), and adenocarcinoma (n=1, CEA=7·7 ng/ml, CA19-9=5·1 u/ml).
Conclusions: 1) Some benign conditions should be strongly taken into account when serum CA19-9 is measured. 2) There are no significant increases of serum CA19-9 values related to different gallbladder epithelial features. 3) Normal serum CA19-9 and CEA cutoffs are not useful as markers of early neoplastic epithelial gallbladder changes.

Endoscopic retrograde cholangio-pancreatography (ERCP) and its complications

M. Doganay, M. Guvel, M. Guler, T. Coskun, G. Daglar and N.A. Kama *Ankara Numune Hospital, 4th Department of Surgery, Türkiye*

Introduction: ERCP is an important method in the diagnosis and the treatment of pancreaticobiliary diseases. The incidence of biliary sepsis is 2–15 per cent in ERCP interventions and it is the most important among the major total complications of ERCP. Thus, in order to evaluate the causes and the complications related to ERCP, having been performed in our 4th surgery clinic, we planned this study.
Patients and methods: 110 patients of 4th surgery clinic who underwent ERCP between the years of 1991 and 1997 were evaluated retrospectively. Patients were evaluated on the bases of; age, gender, ERCP indications, clinical diagnosis, previous biliary surgery, diagnostic method and interventions, performed surgical methods, complications and postoperative morbidity and mortality. The statistical analyses were evaluated with Chi-Square (Pearson) test $P<0{\cdot}05$ were accepted as statistically significant.
Results: In this series of 110 patients, 97 patients (88·2 per cent) underwent ERCP preoperatively and 13 patients (11·9 per cent), postoperatively. In all cases, broad spectrum antibiotics were administered before and after this intervention. 54 (49·1 per cent) patients were male and 56 (50·9 per cent) patients were female. 34 cases were over 65 years old (30·9 per cent) and 76 cases were under 65 years of age (69·1 per cent). Mean age were 55·4 (17–86). The results of ERCP: six patients were assessed as normal (5·5 per cent), 72 patients were assessed as benign (65·4 per cent) but malignant pathology was identified in 32 cases (29·1 per cent) ($P<0{\cdot}001$). ERCP could not be performed in 10 patients due to different reasons (9·1 per cent). After ERCP 9 patients developed biliary sepsis (8·2 per cent), three patients developed bleeding (8·2 per cent), one patient developed common bile duct perforation (0·9 per cent). Another patient died during ERCP due to internal medical pathology. It was observed that 20 cases had been operated for biliary tract problems previously (18·2 per cent) and the complication ratio in this group were 30 per cent ($P<0{\cdot}01$). There were biliary tract dilatations in 80 patients (72·7 per cent) and the complications were found in 11 patients (13·8 per cent) ($P<0{\cdot}05$). Biliary sepsis was not found in patients in whom the ECRP could not pass proximal to the site of the lesion. Nasobiliary stent and transient 7F plastic stent were applied to 4 (3·6 per cent) and 2 (1·8 per cent) patients respectively and the complication rates were 28·6 per cent and 14·3 per cent respectively ($P<0{\cdot}05$). 83 cases were operated (75·5 per cent) perioperative mortality was 6·4 per cent (n=7) and the overall mortality were 15·5 per cent (n=17).
Conclusion: The most important reason for mortality and morbidity after ERCP is biliary sepsis and its rate was found as 8·2 per cent in this study. The complication rates were found to be high in patients with malignancy, previously operated biliary tract, dilatation of biliary tract, nasobiliary stents. We think that the reason why the complication rates were high in nasobiliary stent patients would be the inability to maintain asepsis and to perform adequate drainage from NBS.

The incidental finding of gallbladder carcinoma in elective laporoscopic cholecystectomy – does it fulfil the requirements of oncological surgery?

N. Hennes, M. Aleksic and B. Ulrich *Department of Surgery, Gerresheim Hospital, Gräulinger Str. 120, 40625 Düsseldort, Germany*

Aim: Still we find hints in literature, that the incidentally diagnosed carcinoma of the gall bladder in laporoscopic cholecystectomy is affiliated with a good prognosis. We wanted to investigate retrospectively, whether in our patients this statement is justified.
Material and methods: From October 1987 to August 1997, 28 patients with carcinoma of the gall bladder underwent operation in our hospital. In 13 patients the diagnosis was known preoperatively, in 15 the diagnosis was confirmed intraoperatively (n=5) or postoperatively (n=10). For our retrospective analysis we used the data from our oncological follow-up, in which most of our patients took part.
Results: The prognosis of patients operated under the diagnosis of gall bladder cancer was expectedly poor: only four were operated in a curative manner, their mean survival was 5·5 months. The palliatively operated had a mean survival of only 1 month. All these patients died within 23 months.

The prognosis of incidentally diagnosed gall bladder cancer was poor as well.

In all of our 15 patients the first operation was an open or laparascopic cholecystectomy. A second, extended operation could not be performed in 11 patients due to manifest liver metastasis, lymphangiosis carcinomatosa or lymph node metastasis or poor general condition in elderly patients. Within this group, two are still living, one with manifest liver metastasis (16th postoperative month), the other without tumour evidence (8th postoperative month).

An extended secondary operation was planned in four cases. Since one had liver metastasis found in the second operation, it could be performed in only three. Of these three, one lives for six months, another for 11 months postoperatively without any evidence of tumour recurrence. The third died in the 9th postoperative month of liver metastasis.

Of four patients with T1 stages without second operation, two elderly patients were lost from our follow up, one died in the 13th postoperative month, the other lives in the 16th postoperative month with manifest liver metastasis.
Conclusion: As well as the primary diagnosis of gall bladder carcinoma, the incidental finding of an carcinoma in elective cholecystectomy is affiliated with an extremely poor prognosis. The only option to improve survival time slightly seems to be extended surgery to clear the liver bed of the gall bladder with wide margins. In any case of proved gall bladder carcinoma, the operation should be performed as open surgery. With questionable intraoperative findings, early conversion to open surgery is recommended.

Complex therapy of gallbladder carcinoma

P. Kupcsulik, Z. Rusz, P. Lukovich, K. Darvas and L. Flautner
1st Department of Surgery, Semmelweis University, Üllöi ut 78, Budapest, 1082, Hungary

Malignant tumours of the gallbladder represent an unsolved problem of surgery, with poor immediate and late results. Aim of the study was to evaluate the results of complex oncological therapy of gallbladder carcinoma.

From 1989 to 1997 108 patients for primary malignancy of the gallbladder were admitted to our institutions. 80 per cent of them were female, mean age of the whole group was 66·5 years respectively. Concomitant gallstones were detected in 54 patients (50 per cent). Radical surgery with partial liver resection and/or hilar lymph node block dissection was possible in 36 patients. Biliary or gastrojejunal bypass has been applied for palliation in 24 cases. Advanced tumour mass was found in 48 patients, where only laparotomy, or FNAB was performed. In these group of patients ERC, PTD succeeded in only 20·4 per cent. Chemoembolization as adjuvant treatment after resection was applied in eight cases, for palliation, in four. Percutaneous ethanol injection was used in four cases. Intraarterial chemotherapy via hepatic arterial port was administered in six. Metastases of the primary tumour were seen in the liver (42 patients), regional lymph nodes (10 patients) lungs (5 patients), peritoneum (seven patients), kidney (one patient). Radical resection, with hilar lymph node dissection gives hope for the patients. 62 per cent of radically operated patients are living after two years. Liver infiltration and/or distant metastases represent a poor prognosis however. Palliative endoscopic or transhepatic drainage procedures have minimal chance for success.

Therapeutic options for iatrogenic biliary lesions following open and laporoscopic surgery

D. Ungureanu, D. Ulmeanu and C. Daha *Spitalul Caritas, Clinica de Chirurgie, str. Traian nr, 29, sector 3, Bucuresti, Romania*

Iatrogenic biliary lesions were and still are a very serious event caused by accidental surgical trauma (ligature or section) due to inadequate identification of biliary and vascular elements, or to extensive dissection which damages the vascular microcirculation of the common bile duct, causing ischaemic necrosis with consequent formation of biliary fistulae or stenosis. On the other hand biliary stenosis may occur by using for haemostasis inadequate nonresorbable suture lines, causing granulomatous lesions or sclerosis of the common bile duct. The prognosis for this pathology is closely correlated with the timing of discovery of the lesions.

The authors present their experience on 53 surgical procedures done to correct some incidental injuries of the common bile duct, during 30 years of practice. In this presentation are discussed the essential factors that affect the difficulty of correctional procedures and the technical options reserved for each case.

Particularly aspects of reconstruction, or replacement of the common bile duct are presented, adding some original procedures (hepaticojejunostomy without suture or colangioomphalo-choledocostomy).

Of the many external drainage techniques of the common bile duct, the authors prefer the axial biliary trans-choledocohepatic drainage. It represents one of the only possible procedures after choledochojejunostomy and after hepatico-enteric anastomosis in Glisson's capsule. It is also the elective procedure for drainage and calibration in reparative biliary surgery, or after reimplantation of the common bile duct.

Early failure of intestinal barrier function and endotoxaemia in severe acute pancreatitis

B.J. Ammori, P.C. Leeder, R.F.G.J. King, G.R. Barclay*, I.G. Martin, M. Larvin and M.J. McMahon *Academic Surgical Unit, The General Infirmary, Great George Street, Leeds, UK; *Blood Transfusion Service, Royal Infirmary, Edinburgh, UK*

Aim of the study: This study investigated intestinal permeability in healthy controls and patients with acute pancreatitis, its relationship with severity, and evidence for endotoxaemia.
Materials and methods: Polyethylene glycol (PEG) 400 and PEG 3350 were selected to determine micromolecular and macromolecular intestinal permeability. PEG 400 (5 g) and PEG 3350 (40 g) were administered enterally. Urinary PEG molecules were measured by high-performance liquid chromatography. Samples were completed within 72 hours of symptoms onset. Attacks were classified as mild or severe by the Atlanta Criteria. APACHE-II scores, C-reactive protein (CRP) levels and endotoxin and anti-endotoxin antibodies were determined on admission. There were 75 subjects: 23 healthy controls; 36 mild and 16 severe attacks.
Summary of results: Median admission APACHE-II was 10 in severe and five in mild attacks, median peak CRP 279 mg/l in severe and 90 mg/l in mild attacks. Urinary recovery of PEG 400 was similar in all groups, but that of PEG 3350 was significantly greater in severe attacks (median 0·46 per cent, range 0·04–10·8 per cent) compared with mild attacks (median 0·08 per cent, range 0·05–0·26 per cent) and controls (median 0·12 per cent, range 0·05–0·22 per cent) (both $P<0·001$). Endotoxaemia was detected more frequently in severe compared with mild attacks (50 per cent vs. 22 per cent), and at greater levels (median 0·035 EU/ml vs. 0·01 EU/ml). Anti-endotoxin IgG levels were significantly lower in severe compared with mild attacks (median 65·8 vs. 111 GMU, $P<0·01$).
Conclusion: The results suggest that intestinal barrier function is impaired early in the course of severe acute pancreatitis. This may play an important role in the pathogenesis of Multiple Organ Failure and superinfection of pancreatic necrosis.

Prognostic factors for survival of patients with tumours of the pancreatic head

Cs. Berczi, J. Bocsi*, K. Lapis* and Gy. Balázs *1st Dept. of Surg. Med. Univ. School, 4012 Debrecen, P.O. box 27, Hungary; *1st Intitute of Pathol., Semmelweis Univ. of Med., 1085 Budapest*

Retrospective study was performed to measure the possible prognostic factors for survival after radical surgery in patients with carcinoma of the pancreatic head.

29 patients underwent pancreaticoduodenectomy for cancers of the pancreatic head (n=22) and the papilla of Vater (n=7). In seven patients Whipple's procedure was performed, and pylorus preserving pancreaticoduodenectomy was carried out in 22 cases. Using flow cytometry the authors measured the nuclear DNA content of tumour cells.

Median survival of patients with the carcinoma of pancreatic head was 9·3 months. Survival in patients with cancer of papilla of Vater was 20·5 months. The difference was significant. Tumour size and poor differentiation grade had negative influence on survival in patients with tumour of the pancreatic head region. There was no significant correlation between the lymph node involvement and the survival.

Of the 22 pancreatic carcinomas 14 were diploid and eight were aneuploid. The survival was 10 months in case of diploid carcinoma, and it was eight months in case of aneuploid cancer. Six diploid and one aneuploid tumours occurred in the group of cancer of papilla of Vater. In this group the survival of the patients with diploid tumour was 17 months, and it was 40 months with the aneuploid tumour.

The mean proliferation index (PI) of the diploid pancreatic cancers was 9·7 per cent, whereas that of the aneuploid pancreatic cancers was 13·3 per cent. The mean PI of the diploid tumour of papilla of Vater was 7·5 per cent and the PI of aneuploid tumour was 28 per cent. The PI was significantly higher in aneuploid cases. There was no significant correlation between the PI and the survival.

The survival of high-grade (Grade I-II) pancreatic carcinomas was 10·9 months, and the survival of low-grade (Grade III-IV) tumours was 7·8 months. The low-grade carcinomas occured in a significantly higher rate in aneuploid cases (6/8), than in diploid cases (5/14). The PI was significantly higher in low-grade tumours.

In conclusion, the tumour size and poor differentiation grade were negative prognostic factors for the survival. DNA ploidy and PI had no significant effect on the survival.

Acute pancreatitis: surgical approach in an emergency department

O. Campione, E. Pasqualini, M. Vivarelli, N. Marrano, F. Mancini and A. Avanzolini *Divisione di Chirurgia d'Urgenza – Dir. Prof. O. Campione, Policl.S. Orsola, Malpighi Dipart. Scienze Chirurgiche ed Anestesiologiche, Univ. degli Studi di Bologna, Italy*

Over a 26 month period, from October 1995 to November 1997, 65 patients with acute abdominal pain and suspected acute pancreatitis were admitted to the Emergency Surgery Unit of S. Orsola, Malpighi Hospital in Bologna, Chief Prof. O. Campione.

Clinical diagnosis was supported by typical clinical manifestations and by values of serum amylase and/or serum lipase in excess of three times the upper limit of normal.

Abdominal ultrasound and CT scan were performed within 24–48 hours of hospitalization, in order to confirm the clinical diagnosis and to distinguish interstitial from necrotizing pancreatitis.

33 of 65 patients were males with age ranging from 16 to 87 (average 56), and 32 were females with age ranging from 22 to 95 (average 66).

Among our cases, 47 patients (72 per cent) had biliary pancreatitis and 12 (18 per cent) had alcoholic pancreatitis; in four cases (six per cent) the etiology was post-operative, and three cases (four per cent) had post-endoscopic retrograde cholangiography (ERCP) pancreatitis.

In 17 patients (12 with biliary, three alcoholic and two post-operative pancreatitis) surgery was performed for infected pancreatic necrosis or for sterile necrosis without clinical improvement after one or two weeks of intensive care therapy, or if evidence of organ failure and systemic complications had intensified.

Surgical debridement of necrosis was performed.

Five patients (two with alcoholic, one gallstones and two post-operative pancreatitis) died.

18 out of 47 patients with pancreatitis caused by gallstones (38 per cent) underwent urgent endoscopic retrograde cholangiography which was performed within 72 hours from the onset of symptoms, because of obstructive jaundice and/or biliary sepsis.

In 16 patients (88 per cent) ERCP showed gallstones or sludge in the common bile duct, and a sphincterotomy was performed and gallstones were removed.

Urgent ERCP reduced the severity of pancreatitis and relieved biliary sepsis.

Eight out of 16 patients (50 per cent) didn't undergo cholecystectomy because of high operative risk.

In our experience, a multidisicplinary approach including medical therapy or intensive care therapy according to the severity of pancreatitis, radiologic evaluation, careful monitoring and surgical therapy, represent the optimal management of patients with acute pancreatitis, selecting the strategy best suited to the individual clinical situation.

Effects of gabexate-mesilate on pancreatic juice: experimental and clinical results

R. Caronna, P. Chirletti, L. Diana*, R.N. Lorenzini*, P. Campedelli*, D. Biacchi, A. Bovino, Va. Stipa and V. Stipa *Surgical Pathology IX, Surgical Clinic I, *Istituto Superiore di Sanita', University of Rome 'La Sapienza', V. del Policlinico, 00161 Rome, Italy*

Aim of the study: To assess the pancreatic inhibitory action of Gabexate-Mesilate (GM) in pancreatic juice and serum in an experimental model and in human subjects.

Material and methods: Five female pigs each weighing 130 kg were used for the experiments. After laparotomy, the pancreas was transected and the pancreatic duct cannulated. GM (1000 mg/24 h) was intravenously infused and samples of blood and pancreatic juice were taken at 0, 24, 48 and 72 ore for determination of Phospholipase A2 and amylase activity and GM inactive metabolite (ethyl-p-hydroxy-benzoate).

We also assessed GM activity in four patients: two had pancreatic duct drainage placed after duodenopancreatectomy; and two had pancreatic drainage after pancreatic resection. GM was injected at 900 mg/24 h and samples of blood and pancreatic juice were taken before, during and after G.M. infusion for six days. During the second week, as an adjunct to GM, patients received subcutaneous injection of octreotide (0·3 mg/24 h). Samples of pancreatic juice and serum were assayed for phospholipase A2, amylase and the GM metabolite, and the pancreatic secretion was measured.

Results: In pigs and in human subjects GM infusion led to detectable GM metabolites in pancreatic juice and serum. GM reduced enzymatic activity in serum and pancreatic juice in a dose-dependent manner but left the volume of pancreatic juice unchanged. Conversely octreotide injection left enzymatic activity unchanged but significantly decreased pancreatic secretion in humans.

Conclusions: G.M. acts as an enzyme inhibitor within the pancreatic ducts. This finding confirms the rationale underlying its use in reducing the incidence of severe complications in patients with acute pancreatitis. Combined treatment with octreotide and GM is useful because these two drugs inhibit pancreatic secretion in two different ways.

Nitric oxide and heparin but not procaine improves blood perfusion of the pancreas in acute experimental pancreatitis

M. Dobosz, S. Hać, D. Dobrowolski, D. Dymecki, R. Rzepko and Z. Wajda *II Department of General, Gastroenterological and Endocrinological Surgery, Medical University of Gdańsk, 1, Prof. Kieturakis Street, 80–742 Gdańsk*

The aim of the study was to investigate the influence of a nitric oxide donor (L-arginine), heparin and procaine on the microcirculation of the pancreas in acute cerulein-induced pancreatitis (AP) in rats. AP was induced in 48 rats (12 animals in each group) by four intraperitoneal cerulein injections 15 µg/kg/h. Microcirculatory values of the pancreas were measured by means of laser Doppler flowmetry. The pancreatic capillaries' morphometry (the amount of open/closed vessels, the capillary diameter, sum of open capillaries' areas/mm^2 of the tissue) was carried out upon the capillaries stained with monoclonal antibody against von Willebrand's endothelial antigen. The animals were divided into the groups: Group I – AP receiving no treatment; Group II – AP treated with L-arginine 2×100 mg/kg; Group III – AP treated with heparin 2×2·5 mg/kg; Group IV – AP treated with procaine 2×25 mg/kg. Acute pancreatitis resulted in a fall of pancreatic perfusion to 37 per cent as compared to the basal values of healthy animals, measured by laser Doppler flowmetry. L-arginine and heparin injections improved the pancreatic perfusion to 72 per cent and 76 per cent respectively. In the group I the percentage of open capillaries was calculated as 37 per cent. L-arginine and heparin treatment increased the amount of open capillaries up to 52 per cent and 54 per cent. The L-arginine and heparin administration increased twice the sum of open capillaries' areas as compared to the AP group without treatment. Procaine therapy had no effect on impaired pancreatic microcirculation in AP. Authors conclude that nitric oxide and heparin improve the pancreatic blood perfusion in AP and may be considered as therapeutic agents preventing the pancreatic necrosis.

Endocrine function of the pancreas following storage with HTK or UW solution and transplantation

U.J. Hesse, R. Troisi, B. Jacobs, S. De Laere, F. Berrevoet and B. de Hemptinne *Department of Surgery, University Hospital, De Pintelaan 185, 9000 Gent, Belgium*

HTK (Histidine Tryptophan Ketoglutarate) solution is used with increasing frequency for cardiac, renal and hepatic transplantation. For pancreatic grafts this solution has not been used routinely, essentially due to the lack of experimental data. In the following study HTK solution was used compared to UW solution for 24 hours cold storage of porcine segmental pancreatic grafts prior to autotransplantation.

Material and methods: Landrace pigs underwent total pancreatectomy including the coeliac trunk, the splenic artery and the proximal common hepatic artery as arterial vascular pedicle and the splenic vein as the venous vascular pedicle. The arterial pedicle was flushed ex situ, either with HTK (GI) or UW (GII) (50 to 100 cc until the venous effluent was clear for at least 5 minutes, perfusion pressure 60 cm H_2O). Thereafter the grafts were stored for 24 hours at 4°C. For the induction of diabetes the right lobe of the pancreas was totally resected with preservation of the duodenal arcade. After 24 hours the pancreas was transplanted to the iliac fossa. Exocrine drainage was performed into the peritoneal cavity. Daily fasting bloodglucose levels were normal <100 mg/dl and glucosuria was absent. Untreated unoperated pigs served as normal controls and totally pancreatectomized animals served as diabetic controls. IVGTT was performed within seven days post-transplant by intravenous injection of 0·5 g/kg glucose and sampling serum glucose at 0–1–3–5–10–20–30–60–90 and 180 minutes. K-values were calculated.

Results: In GI (HTK) 8/8 were normoglycemic after transplantation. The mean K-value was −1·33±0·81. Glucosuria was absent in all animals. In G II (UW) 6/6 animals were normoglycemic; the mean K-value was −1·50±0·83 (P vs GI 0·45). Mean K-value of totally pancreatectomized animals was −0·52±0·19 (P<0·008 vs functioning grafts). Glucosuria in pancreatectomized animals was maximal. The mean change in wet weight of the pancreas grafts was 3·01±2·2 g in GI and −1·0±3·6 g in GII (P=0·17).

Conclusion: 24 hours cold storage (4°C) of the porcine pancreas, using HTK solution provides reliable graft function following autotransplantation as obtained for storage with UW solution.

Repeated laporotomy for infected pancreatic necrosis

M.I. Pirski, M. Śmietański, D. Zadrożny, M. Lukiański and T. Draczkowski *I Department of Surgery, Medical University of Gdańsk, Debinki 7, 80–211 Gdańsk*

Aim: Evaluation of the method of repeated laporotomy in patients with infected pancreatic necrosis.

Material: In the years 1984–1997, 48 patients with infected pancreatic necrosis were treated by the repeated laporotomy. The most common reason of infected necrosis was acute pancreatitis (25 patients) and as a complication of ERCP (six patients). In all cases an elevated body temperature was noted, and in 16 patients initial signs of multiorgan failure were noted. Necrosis was visualized by ultrasound in 62 per cent of cases (23 patients), and by CT scans in 100 per cent.

Results: All patients were treated according to Bradley's procedure. 11 hospital deaths (37 per cent) were noted. Most common reason was multiorgan failure (14 patients). In 12 patients (23 per cent) complications were noted. These were: jejunal and colic fistulae and bleeding from retroperitoneal vessels. The follow-up period of 28 living patients was three months to 13 years. During this time proper endo- and exocrine function of the remaining pancreatic tissue and lack of any fluid collections were documented.

Conclusions: Repeated laporotomy is an effective method of treatment of patients with infected pancreatic necrosis. It enables proper view of the retroperitoneal space and good control in complicated cases.

Fulminant pancreatitis

M.A. Secchi, G.A. Raimundo, L. Quadrelli, E. Tagliaferri, M. Brogliatti, A. Nosti, L. Rossi and J. Maraver *Hospitales Italiano, Provincial and Clemente Alvarez, Rosario, Argentina, Riobamba 524 (2000), Rosario, Argentina*

In 1992 a clinically-based classification system for acute pancreatitis (AP), was proposed at Atlanta Symposium. Fulminant pancreatitis (FP) is a non-agreed definition, but some patients with severe AP develop an early fulminant and lethal progress of the disease. For defining FP, we propose those severe AP cases which, within the first 48 hours of the onset of the symptoms, show failure in three or more organs (multisystemic organ failure: MOF).

Methods: Patients having AP of any etiology were prospectively studied in three surgical centers over the last seven years. Our aim was to analyse fulminant cases in severe AP, and we detected incidence, etiology, organ involvement in MOF and mortality. Severity was determined by APACHE II (severe cases: >15 points) and our Original INDEX (severe cases: >0·40). Mortality referred to those hospitalized cases.

Results: 48 severe cases were detected, and 13 (27 per cent) were fulminant. Etiology was gall stone in six, alcoholic in four, dislipemic in one, post ERCP in one, and post surgical papillotomy in one. All of FP were MOF with these organ functions involved: lung and kidney in all 13, heart in 9, liver in 8, endocrine pancreas in 8, brain in 8, hemostatic in 3. The mean APACHE II average was 27±6 and the INDEX was 0·54±0·6. All patients were treated in ICU with a multidisciplinary approach, and 11 of 13 (85 per cent) died after many complications during the treatment. Mortality in non-fulminant severe cases was 4 of 35 (11 per cent) (X2: $P<0{\cdot}01$).

Conclusion: Fulminant pancreatitis is a special entity in severe cases of AP with a MOF detected before 48 hours after the onset of the symptoms, with a mortality of 85 per cent of the patients. Necessity of an agreed definition is mandatory to perform new treatment modalities and strategies to subdue this lethal entity.

Acute pancreatitis – diagnostic and surgical procedures in Poland – 15 years review

Z. Wajda, Z. Gruca, Z. Sledziński, J. Reszetow, L. Kaska and W. Makarewicz *II Department of General, Gastroenterological and Endocrinological Surgery, Medical University of Gdańsk, 1, Prof. Kieturakis Street, 80–742 Gdańsk, Poland*

We analysed inquiries from 71 surgical units in Poland in the period 1981–1991. The inquiry consisted of the following parts: number of cases of AP in the last 10 years, sex, age, etiological factor, form of AP, diagnostic tools, treatment modalities, mortality rate. In the period 1981 to 1991, 8866 patients with AP were admitted to surgical departments (4300 male and 4566 female). The average age was 52·2 years, patients' age ranged between 16–81 years. The data concerning 230 cases of AP treated from 1968 to 1996 were precisely analysed (139 female and 91 male, average age 51). The patients were stratified according to the Trapnell's and APACHE II scores. Patients were divided into two groups: Group A – included 16 patients treated between 1968–1985. Group B – included 30 patients treated from 1986 up to 1995. The data of 8866 patients with acute pancreatitis – biliary in 53 per cent, alcohol and other in 47 per cent. 74 per cent had oedematous pancreatitis, 26 per cent necrotizing form of the disease. In four per cent of all the patients computed tomography was performed. 66 per cent of patients were treated conservatively with the mortality rate of 3·5 per cent. 34 per cent of the patients underwent surgery with the mortality rate 23 per cent. Data collected by the authors (230 patients with AP) revealed biliary pancreatitis in 56 per cent of the cases and in 44 per cent the alcohol etiology. Oedematous form of AP was diagnosed in 73 per cent, necrotizing pancreatitis – in 17 per cent of the cases. In 46 patients with necrotizing pancreatitis, bacterial infection was confirmed. These 46 patients are the subject for the further analysis in this work. Mortality rate in the patients of group A was 81 per cent. The mortality rate in group B significantly decreased to 48 per cent. Hospital stay period of the patients that survived infected AP was between 27 to 122 days.

POSTER PRESENTATIONS

Spleen

The effect of splenectomy and splenic autotransplantation onto blood lipid levels

S. Demirer, N. Sengül, S.G. Terzioğlu, B. Güngör, A. Akan and A. Doğrar *Department of General Surgery, Ankara University School of Medicine, Ibn-i Sina Hastanesi, 06100, Yenisehir, Ankara, Turkey. Department of Biochemistry, Ankara Numune Hospital, Ankara Numune Hastanesi, 06100, Yenisehir, Ankara, Turkey*

Experimental and clinic studies have been shown that spleen may have some effect on the lipid metabolism. It has been shown that serum cholesterol levels have been found to be low in patients with hypersplenism and this has been reversed to normal levels following splenectomy. Also the incidence of atherosclerotic cardiovascular disease has increased in patients who have had a splenectomy following trauma.

In the current study, the effect of splenectomy and splenic autotransplantation on the blood lipid levels were investigated. Forty rats were studied and preoperative total triglyceride, total cholesterol, HDL, LDL and VLDL levels were determined.

Rats were classified to five groups based on the surgical procedures.

Group S	(*n*=8 rat)	Sham group
Group SP-N	(*n*=8 rat)	Splenectomy + normal diet
Group SP-C	(*n*=8 rat)	Splenectomy + % 1 cholesterol diet
Group SA-N	(*n*=8 rat)	Splenicautotransplantation + normal diet
Group SA-C	(*n*=8 rat)	Splenicautotransplantation + % 1 cholesterol diet

An active splenic function was shown in rats who underwent splenic autotransplantation in both groups by using technician 99m sulphocolloid scintigraphy on day 30. Blood lipid levels were repeated 6 months later.

There was no difference between pre and postoperative lipid levels in sham group and SA-N group ($P>0·05$). All lipid levels including HDL are increased significantly in SP-C group ($P<0·05$). Also, VLDL and total triglyceride levels are increased significantly in SP-N and SA-C group ($P<0·05$).

This study showed that the spleen may have an important effect on the lipid metabolism and splenic autotransplantation may be protective in conditions in which the lipid levels are increased.

Eleven years of experience in nonoperative management of splenic injuries

B. Oller, M. Armengol, N. Rodríguez, J. Gener, A. Olazábal, M.D. Salvia and M.A. Broggi *Department of General Surgery, Hospital Universitari Germans Trias i Pujol. Apartado de correos 72, 08916 Badalona, Barcelona, Spain*

Aim: To evaluate the effectiveness of a conservative policy initiated in 1986 with regard to splenic injuries.

Materials and methods: From 1986 to the present, all patients with abdominal injuries, admitted to our hospital, who were haemodynamically stable, were given computed tomography (CT) to detect visceral intra-abdominal injuries. If the existence of splenic injury was confirmed, the therapeutic protocol was based on complete bed rest, and monitoring of the hemodynamic condition. Surgical exploration was only performed in the presence of one of the following conditions: penetrating abdominal injury, associated abdominal injuries which required surgery, blood dyscrasia, abnormal spleen, or persistence of haemorrhage (after the administration of up to four units of packed red blood cells) or recurrence of the haemorrhage.

Results: Two hundred and three patients, 166 male and 37 female, were admitted with splenic injuries during the study period. Ages ranged from 8 to 87 years old (mean 29·9). The principal mechanism of injury were vehicle accidents (132 cases). In eight patients immediate surgical intervention was necessary, in the other 195 patients, a conservative protocol was followed and in only 42 cases was surgical intervention necessary because of the afore-mentioned indications. Intervention was carried out at the moment of hospitalization or during the observation period. In 153 cases, spontaneous resolution of the splenic injury was achieved and confirmed by CT with an average hospital stay of 28 days; 56 of these patients needed a transfusion (mean 2·8 units of blood) and five patients died as a result of irreversible neurological injuries.

Conclusion: In our experience, early laparotomy in splenic injuries may be substituted for a nonoperative therapy protocol, whatever the age of the patient, with surgical intervention indicated for limited cases only.

Appendix

Diagnostic laparoscopy to exclude appendicitis is only useful in women of child bearing age

F.G. Bergin, I.P. Mackie, E.L. Gilliland, A.L.G. Peel and D.J. Leaper *Professorial Unit of Surgery, North Tees General Hospital, Stockton-on-Tees, Cleveland, United Kingdom*

Aim: A prospective audit of diagnostic laparscopy for patients with suspected appendicitis was revisited after a two year period to 'close the loop'. Open appendicectomy is encouraged as a training operation at this hospital.

Material and Methods: Two hundred and eighty two patients were taken to theatre with a suspected diagnosis of acute appendicitis. Of these 145 (51 per cent) had laparoscopy; 116 had subsequent appendicectomy. The remaining 137 patients (49 per cent) had appendicectomy without preliminary laparascopy (the majority being men or children with clear signs and symptoms).

Results: Twenty nine patients were spared unnecessary appendicectomy following laparoscopy; all but one being women of child bearing age. However, 116 patients had appendicectomy, of whom 31 (21 per cent) had a clinically and histologically normal appendix; 85 (59 per cent) were inflamed with 23 (16 per cent) perforations. Of those who did not have laparoscopy 29 (21 per cent) had a normal appendix removed, 108 (79 per cent) were inflamed with 35 (32 per cent) perforations. Operating times were prolonged in the laparoscopy group (62 min; range 2–240) compared to open operation alone (53 min; range 15–250). There were no differences in length of postoperative stay (4·2 days, range 1–16 vs 4·6 days, range 1–17).

Conclusion: Women of child bearing age benefit from preliminary diagnostic laparoscopy to avoid unnecessary open operation. For all other patients open appendicectomy is appropriate based on clinical signs and symptoms and should be retained as a training operation.

Duration of symptoms is not related to pathology in acute appendicitis

B. Chmiel *Department and Clinic of General Surgery of Silesian Medical University, 20/26 Francuska str., 40-027, Katowice, Poland*

Aim: To detect relationship between duration of symptoms and histologically proven appendiceal inflammation level.

Material and methods: One hundred and forty six patients who underwent appendicectomy at one institution between January 1991 and October 1995 have been surveyed. Patients with other aetiologies of an acute abdomen (adnexitis, rupture of ovarian cysts, torsion of greater omentum) were excluded. The group consisted of 108 male and 38 female with age range between 14 and 68 years.

Results:

	Duration of symptoms (hours)					
Groups	Mean	Median	Minimum	Maximum	Standard deviation	Skewness
Catarrhal appendicitis	43·7	24	5	144	5·2	1·23
Phlegmonous appendicitis	36·1	24	6	120	30·8	1·45
Gangrenous appendicitis	41·6	24	12	140	32·9	1·75

Duration of symptoms did not differ significantly between groups (Kruskal-Wallis ANOVA median test).

Conclusion: The stage of inflammatory process during acute appendicitis does not depend on duration of symptoms.

Schistosomal appendicitis

A.-W. N. Meshikhes and C. J. Chandrashekar* *Departments of Surgery and *Pathology, Dammam Central Hospital, Dammam, Saudi Arabia*

Aim: The appendix is commonly infested in schistosomiasis. It is not known if this is a predisposing factor for appendicitis or a mere coincidental histological finding.

Material and methods: A total of 56 patients (51 males; 5 females) underwent appendictomy for 'schistosomal' appendicitis over 10 year period. The histological slides of 41 (73·2 per cent) patients were retrospectively studied.

Results: The highest incidence was in the age groups 21–40 years. All excised appendices showed ova within their walls especially in the submucosal layer. The most common tissue response were submucosal fibrosis (92·7 per cent) and eosinophilia (87·8 per cent), followed by presence of suppurative inflammation (80·5 per cent). Granulomatous reaction was evident in 13 cases only (31·7 per cent). A striking feature was atrophy of submucosal lymphoid follicles in 70·7 per cent of cases. Hyperplasia of lymphoid follicles and serosal granulomas were rare (2·4 per cent). Similar tissue responses were histologically seen in four normal appendices examined.

Conclusion: Appendiceal infestation may predispose to appendicitis in the majority of affected cases but in some cases, it may well be a mere coincidental histological finding. Preoperative knowledge bears no clinical significance and does not alter management. However, the search for and treatment of active disease may be lacking in areas where follow up is a problem.

Acute appendicitis: impact of ultrasonographic visualization of the normal and abnormal appendix

Z. Tarján and T. Winternitz* *Department of Radiology and *1st Department of Surgery, Semmelweis Medical University, Ulloi ut 78/a, 1082 Budapest, Hungary*

Aim: To improve the accuracy of clinical diagnosis in patients with suspected appendicitis, an attempt was made with high resolution broad band width (5–10 MHz) ultrasound transducers to visualise both the normal and abnormal appendix.

Material and methods: One hundred consecutive patients were evaluated. The visibility of the appendix, its AP outer diameter during compression (OD), the maximal wall thickness (MWT) and the presence of colour Doppler (CD) signs were recorded in all cases. The sonographic results were compared to operative and pathological results in all operated cases (38) and in 62 cases a 2 weeks clinical follow up was made.

Results: The appendix was visualised in all pathologically positive cases and in 82·5 per cent of the normal appendices (18·7 per cent partly, 63·8 per cent in whole length). The OD was greater than 6 mm in all true positive appendicitis cases, but also in seven of the normal appendices. Thus, using larger than 6 mm OD as the sonographic criteria of appendicitis resulted in unnecessarily operated false positive cases (100 per cent sensitivity, 91·3 per cent specificity, 74 per cent positive predictive value and 100 per cent negative predictive value). The false positive rate decreased, but the sensitivity also, if using MWT>3 mm as the diagnostic criteria (90 per cent sensitivity, 97·5 per cent specificity, 90 per cent positive predictive and 97·5 per cent negative predictive value). Adding CD improved specificity, but decreased sensitivity in both methods.

Conclusion: The normal appendix can be detected more frequently by ultrasonography than reported previously. Whole length demonstration of an appendix, smaller has 6 mm in OD is 100 per cent specific for a normal appendix. This sign might prevent unnecessary laparotomies in clinically doubtful cases. However, sonographic visualization of the appendix does not solve all diagnostic problems. While smaller than 6 mm OD means normal appendix, larger diameters do not necessarily indicate appendicitis. The specificity can be increased if MWT and CD signs are also evaluated.

Increased serum lipofuscin after renal transplantation

B. Chmiel *Department and Clinic of General Surgery of Silesian Medical University, 20/26 Francuska str., 40-027, Katowice, Poland*

Lipofuscin is believed to be the last product of lipid peroxidation. Elevated serum lipofuscin is a prognostic factor of multiple organ failure after major surgery.
Aim: To compare serum lipofuscin level after renal transplantation, hemodialysed patients and well matched healthy adults.
Material and methods: Lipofuscin has been determined according to Tsuchida with Roumen's modification and expressed in arbitrary units (u.), in serum of 56 healthy adults, 16 renal transplant recipients and nine hemodialysed patients. Age and sex were not significantly different between groups. Serum creatinine and urea levels did not differ significantly between hemodialysed and transplanted patients. Blood was collected before hemodialysis in uremic patients, or within 12 h and 7, 14, 21 days after renal transplantation.
Results: Serum lipofuscin in healthy adults was 231±69 u. In hemodialysed patients and renal recipients was increased significantly to about 150 per cent (364·6±150 u.) and 250 per cent (577±188 u.) respectively. Patients with transplanted kidney have revealed elevated serum lipofuscin level during 21 days after transplantation.
Conclusion: Elevated serum lipofuscin levels after renal transplantations show high oxidative stress due to several mechanisms of lipid peroxidation in this group of patients.

Selective continuous portal heparinization (SCPH) as a therapeutic approach of portal thrombosis after liver transplantation

L. Herrera, E. Martino, J. Castillo, F. Hernanz, F. Casafont, E. Fábrega, D. Casanova and M. Gómez Fleitas *Hospital Universitario 'Marqués de Valdecilla', 39008 Santander, Cantabria, Spain*

Background: Portal thrombosis is a major problem after liver transplantation. Many protocols have been designed in order to avoid and/or prevent it, but, so far, none of them have shown clear advantages.
Aim: To determine the feasibility of portal thrombosis prevention after liver transplantation by continuous portal heparinization.
Material and methods: A 68 year old male patient with a Child B, HCV-related liver cirrhosis and hepatocarcinoma was transplanted at our institution on November 12, 1977. He was an Okuda stage II and preoperative studies did not show any portal thrombosis or other liver transplant contraindications. Preoperative selective chemoembolization was performed. Orthotopic liver transplantation (OLT) with a modified piggyback technique was performed, as we have done in all of our liver transplantations (202). During the hepatectomy, at the moment of portal section, a recent partial thrombosis was found. After thrombectomy, a peroperative histological examination confirmed our impression, excluding a neoplastic origin. Conventional OLT technique was performed and the graft was adequately perfused through the portal vein after usual anastomosis. No other problems were seen. At the end of the procedure, macroscopic findings of portal hypertension were found and a venous catheter (VC) was placed into an ileal branch of the superior mesenteric vein. A peroperatory angiography showed a complete portal thrombosis without any problem from the anastomosis. The VC was left placed and sodium heparin (5000 UI/24 h) was perfused through it. Standard triple therapy immunosuppression was started.
Results: After transient cholestasis, biological data and patient's recovery corresponded to good graft function and a Doppler ultrasonography (DUS) performed 12 hours postoperatively showed a portal permeability with adequate flow patterns. Because of systemic anticoagulation, heparin was changed to subcutaneous low molecular weight (5000 UI/24 h), six days after OLT. A portal angiography by VC showed an adequate portal image of the graft. The VC was removed 15 days after OLT. A new DUS performed 27 days after OLT, showed a good portal flow. The patient progressed well and was discharged on December 12, 1997, 30 days after OLT. Liver pathological findings showed virus C active cirrhosis and hepatocellular carcinoma, major diameter 4·5 cm, in the right lobe without vascular invasion. Chronic, non tumoral, portal thrombosis was also found.
Conclusion: SCPH may be an easy and effective method to manage the portal thrombosis after OLT.

Clinical indications for liver transplantation influence the early acceptance of liver grafts

A. Minguela, *F. Sánchez-Bueno, L. Marin, A. Torío, M. Muro, J.M. Alemany, A.M. García, †M. Miras, *P. Parrilla and M.R. Álvarez *Immunology, *Surgery and †Digestive Sections, Hospital Virgen Arrixaca, Murcia, Spain*

Aim: Acute rejection (AR) remains one of the primary complications during first weeks after liver transplantation even using modern immunosuppressive therapies. Different factors in recipients which could affect the immunological acceptance of the graft are analysed in this study.
Material and Methods: Influence in liver graft rejection or acceptance of patient's age, sex, clinical indication for transplant, immunosuppressive therapy (Cyclosporin-A, -CyA-, Conventional vs Neoral), CyA serum-levels and HLA-compatibility, was analysed in 127 recipients.
Results: Clinical indications for liver transplant with the highest AR-rate were Primary Biliary Cirrhosis -CBP- (60 per cent, 9 out of 15), Chronic active hepatitis-C (57 per cent, 16 out of 28) and retransplant (45 per cent, 5 out of 11); in contrast those with the lowest AR rate were Chronic active hepatitis-B (11·1 per cent, 1 out of 9), amyloidosis (12·5 per cent, 1 out of 8), carcinoma (16 per cent, 2 out of 12) and Alcoholic Cirrhosis (27 per cent, 10 out of 26). Histologically confirmed AR-rate in conventional and Neoral CyA treatments were 33·9 per cent (36 out of 106) and 52·4 per cent (11 out of 21). Patient groups treated with CyA-conventional or CyA-Neoral showed similar age and sex distribution, HLA compatibility degree or post-transplant CyA serum-levels. AR was more frequently observed within younger patients (39·9±18 vs 47·2±16 years, P<0·022) and females (53·8 per cent vs 32·6 per cent; P<0·05). The higher number of patients with CBP, retransplant and Chronic active hepatitis-C among women and CyA-Neoral group might explain their higher AR-rate.
Conclusion: Clinical indication for liver transplantation may influence liver-graft acceptance, irrespective of immunosuppressive therapy and donor/recipient HLA compatibility. This fact should be considered especially when AR-rate is studied in small recipient groups.

Chronic rejection in liver transplantation: effect of HLA matching

M. Muro, *F. Sanchez-Bueno, L. Marín, A. Torío, A. Minguela, J. Sanchís, *P. Parrilla, †J. Bermejo, A.M. Garcia-Alonso and M.R. Álvarez-López *Immunology, *Surgery and †Pathology Sections, H.U. Virgen de Arrixaca, Murcia, Spain*

Aim: Rejection is still an important problem in liver transplantation and, although different reports show distinct and sometimes contradictory views about the role of histocompatibility in liver rejection, there is evidence that HLA antigens are involved in cellular immune response leading to the rejection process. In this way, this study was carried out to examine the effect of the HLA compatibility between liver transplant donor-receptor pairs and their relationship with chronic rejection apparition.
Material and methods: HLA class I and class II typing was performed following a standard complement dependent microcytotoxicity assay and PCR-SSOP method. One hundred and sixty-five liver transplants were included in this study. Re-transplants were excluded from the analysis. The diagnosis of chronic rejection was based on the conventional clinical and anatomopathological criteria. The relationship between HLA compatibility and the chronic rejection episodes was compared using the X^2 test using an OMS EPI-INFO program.
Results: Analysis was done comparing the compatibility in HLA-A, -B, -DR (serologic) and HLA-DRB1, -DQB1 and -DPB1 with the occurrence of chronic rejection. Only HLA-A compatibility shows statistical significant differences. Among the transplants performed with zero HLA-A matches, the percentage of chronic rejection was 2·8 per cent (3/107), whereas in those with 1 or 2 matches this percentage was 8·5 per cent (4/47) and 75 per cent (3/4), respectively. These differences were statistically significant (P=0·00007).
Conclusion: In summary, the observed results indicate that HLA-A matching could be relevant in the development of chronic rejection in liver transplant recipients.

Long term results of liver transplantation in four siblings from the same family with familial amyloidotic polyneuropathy (FAP) type I TTR Ala-71

P. Ramirez, F.L. Andreu, F.S. Bueno, R. Robles, P. De Mingo, M. Miras, F. Acosta, J.M. Rodriguez, J. Lujan, V. Munitiz, A. Rios, M. Munar and P. Parrilla *Liver Transplant Unit, Virgen de la Arrixaca University Hospital, El Palmar 30120, Murcia, Spain*

We report the evolution of the polyneuropathy of the extremities and autonomic dysfunction in four sibling patients, from the same family, with the Ala-71 variant treated by liver transplantation (LT). To our knowledge, this is the first world report with this TTR-variant. The specific diagnosis of FAP I was investigated by detection of Ala-71 in serum using the monoclonal antibody FD6 by ELISA technique.

The four siblings are alive from two to five years after LT. After the operation, the seriated determinations of TTR-Ala-71 variant showed a decrease in serum levels in all cases.

In all the patients we noted clinical improvement of the polyneuropathy of the extremities and autonomic dysfunction after LT. However, no patient showed an improvement from the electromyographic point of view. There were a progression of the vitreous amyloid deposits after LT in the three affected patients, likely in relation to TTR synthesis at level of the coroideous plexus. The female patient had a healthy baby 18 months after LT.

In conclusion, the four patients have significantly improved their quality of life after LT.

Life quality and recurrence of alcoholism in alcoholic cirrhosis patients following liver transplant

P. Ramirez, D. Megias, R. Robles, F.S. Bueno, J.M. Rodriguez, M. Miras, F. Acosta, V. Munitiz, A. Rios, D. Barcia and P. Parrilla *Liver Transplant Unit, Hospital V. Arrixaca, El Palmar 30120, Murcia, Spain*

Aim: To analyse the life quality and recurrence of alcoholism in alcoholic cirrhosis patients after liver transplant.
Patients and methods: We studied 43 cirrhotic transplant patients divided into two groups, alcoholic cirrhotics (26 cases) and non-alcoholic cirrhotics (17 cases). Life quality was assessed by the Nottingham test, quantification of hospital dependence and rate of return to work. Alcoholic recurrence was assessed by questionnaire, and the alcoholic's post-transplant rate of depression by the Beck test.
Results: 1. The Nottingham test showed a significant improvement ($P<0{\cdot}01$) after transplant in both groups of cirrhotics, with no differences between the two. 2. The sick leave rate after operation decreased with time in both groups, but without significant differences compared to the pre-transplant situation. 3. The alcoholic patients' rate of depression showed an extraordinary post-transplant improvement ($P<0{\cdot}001$). After a mean follow-up of 2 years, only 1 patient (3·8 per cent) presented alcoholism recurrence.
Conclusions: The life quality of alcoholic cirrhotics improves significantly after liver transplant. The recurrence of alcoholism is very infrequent.

Primary cardiac allograft failure after carbon monoxide poisoning

I. Rodrigus, V. Conraads, H. De Raedt, R. De Paep, L. Haenen, F. Rademakers and A.C. Moulijn *University Hospital Antwerp, Department of Cardiac Surgery, Wilrijkstraat 10, B-2650 Antwerp-Edegem, Belgium*

Introduction: Due to the present organ donor shortage, donor selection criteria are being progressively liberalized. We present a case of carbon monoxide poisoning that led to primary allograft failure. Biventricular assist device was used as a bridge to recovery.
Donor history: The donor heart had been harvested from a 31-year-old woman who died after smoke inhalation in a house fire. The carboxyhemoglobin levels was 36 per cent. After a short period of cardiopulmonary resuscitation and hyperbaric oxygen therapy the carboxyhemoglobin level decreased to 4 per cent with good cardiac function on echocardiography and a normal ECG. Heart, kidneys, liver and pancreas were harvested after brain death.
Receptor history: The receptor was a 62-year-old man with ischemic cardiomyopathy. Orthotopic heart transplantation was performed with an ischemic time of 120 minutes. Weaning from cardiopulmonary bypass (CPB) was unsuccessful despite additional reperfusion, AV pacing, maximal inotropic support and intraaortic balloon counterpulsation. The Abiomed BVS 5000 biventricular assist device (BIVAD) was implanted. Allograft function improved gradually on serial echocardio-graphy within 24 hours after transplantation, although severe mitral regurgitation was noted during weaning. BIVAD explanation was performed on the fifth day. Mitral valve exploration revealed chordal rupture and erosion of the left ventricular wall by the left atrial cannula. A Carpentier Edwards mitral valve was implanted, followed by successful weaning from CPB. Recovery was complicated by Aspergillus pneumonia treated with amphotericin B and itraconazole. Renal insufficiency required temporary hemodialysis. The patient was discharged after 3 months with excellent cardiac function.
Conclusion: 1. Hyperbaric oxygen therapy is an effective treatment for carbon monoxide poisoning, but brain cells and myocytes are extremely vulnerable. Normalization of carboxyhemoglobin level does not implicate immediate full recovery of energy depleted myocytes. Caution is warranted to accept those hearts for transplantation. 2. Primary cardiac allograft failure can be managed by BIVAD implantation as bridge to recovery or to urgent retransplantation. 3. Incorrect cannula placement demands repositioning even with good BIVAD function.

Apoptosis in chronic rejection of human liver allograft

P. Sotonyi, G. Demirci and B. Nashan *Klinik für Abd. und Transplantationschirurgie, Medizinische Hochschule Hannover, Germany. Medizinische Hochschule Hannover, Transplantationslabor Stadtfelddamm 65, Hannover 30625, Germany*

Introduction: Apoptosis, also called programmed cell death, is one of the most important factor in the pathogenesis of various liver diseases. Apoptosis is presented at low rate in normal human liver as a physiological effect of the liver cell homeostasis and at a higher rate several liver diseases. Two proteins with different activity are of major interest in apoptosis, i.e. FAS/APO-1 located mostly at the surface of hepatocytes and Bcl-2 found at the site of bile ducts. Since chronic liver rejection is characterized by loss of bile ducts (vanishing bile duct), arteriopathy and fibrosis, at least two different pathophysiological aspects can be assumed: T-cell mediated inflammation of epithelium structures and parenchymatosus scaring promoted by macrophages and lipocytes. In order to analyse both presumed pathways, we investigated the expression of FAS/APO-1 and Bcl-2 in comparison with lymphocyte and macrophage distribution in chronic rejected liver allografts.
Material and methods: Biopsy specimens from 10 chronic liver allograft rejection cases were evaluated and compared with eight normal liver controls. TUNEL staining was performed to identify the apoptotic cells. FAS/APO-1 and Bcl-2 expression was assessed using immunohistochemistry. In addition lymphocyte subsets and macrophages were stained (CD3, CD4, CD8, CD20, CD56, 25F9, 27E10).
Results: 1. Increased rate of apoptosis was detected in pericentral hepatocytes and moderate increase in bile duct cells. 2. Bcl-2 expression was markedly upregulated on lymphocytes around the bile ducts, while only few staining of Bcl-2 was visible in pericentral areas and on biliary epithelium in comparison with normal controls. 3. FAS was moderately expressed on pericentral hepatocytes and in bile ducts. 4. T-cells showed dense infiltrat around bile ducts, while B-cells and Nk-cells would not be detected. Conversely macrophages were found only in pericentral areas.
Conclusion: Bcl-2 was downregulated at the site of bile ducts, while increased FAS/APO-1 expression would be demonstrated. These findings suggest an increased apoptosis rate, most likely triggered through the T-cell infiltrate.

Imaging strategy of small bowel Crohn's disease

T. Dévai, Zs. Tarján, E. Makó, L. Duffek, G. Tóth and Á. Mester
Department of Radiology, Semmelweis Medical University, Ulloi ut 78/a, 1082 Budapest, Hungary

Aim: On the basis of our experiences we retrospectively evaluated our patients with small bowel Crohn's disease (SBCD). The purpose of our study was to determine the most efficient diagnostic protocol (enteroclysis, CT, US, immunoscintigraphy) in different stages of the disease.
Material and methods: From 1990 to 1994 we diagnosed SBCD at 144 patients (20 per cent of all patients). We performed enteroclysis and small bowel CT at all patients, abdominal US in almost all patients and in 60 patients 99mTc AgAb immunoscintigraphy. Based on the results of enteroclysis patients were divided into three main groups: early, intermediate and advanced stage of SBCD.
Conclusion: The best protocol in early stage of SBCD is enteroclysis and immunoscintigraphy, CT and US are not necessary. US was effective only if the examination was performed with graded compression (GrUS). CT and GrUS yielded usually positive results if the small bowel wall was thickened. In intermediate and advanced stages all examinations (enteroclysis, CT, US, immunoscintigraphy) showed the pathology. We preferred enteroclysis and small bowel CT to determine the axial involvement and staging of SBCD. GrUS is useful to detect the layers of the bowel wall, the mesenteric proliferation and lymph nodes. With immunoscintigraphy we can identify the areas of the activity of the disease.

Surgical treatment of Meckel's diverticulum

V. Kulic, R. Djordjevic, M. Smiljkovic, A. Kitanovic, M. Gajic and M. Jovanovic *Health Centre Krusevac, Department of Surgery, Krusevac, Yugoslavia*

Aim: We present the results of surgical treatment of Meckel's diverticulum (MD), the most common true diverticulum of the gastrointestinal tract. This is a congenital diverticulum that results from incomplete closure of the omphalomesenteric duct.
Material and methods: During the period 1993–1997 a total of 21 patients with MD were surgically treated in our hospital. These have been retrospectively analysed.
Results: There were 13 (61·9 per cent) clinically symptomatic MD and 8 (38·1 per cent) asymptomatic MD, found incidentally at laparotomy. Complications of MD included intestinal obstruction in eight, acute diverticulitis in four and peptic ulcer in one case. Resection of the segment of ileum bearing the diverticulum was performed in 14 cases and resection of the diverticulum in two cases. Ectopic gastric mucosa, large bowel mucosa, pancreatic tissue and neoplasms were verified on histopathological biopsy. Wound infection as complication were found in two cases. Mortality was 0 per cent.
Conclusions: Treatment of symptomatic MD is by intestinal resection and end-to-end anastomosis in one layer. Asymptomatic MD requires no treatment in adults. Segmental ileal resection (if the base is wide) or prophylactic diverticulectomy (if the base is narrow) is required for prevention of diverticular disease in childhood.

The incidence and results of treatment in case of bleeding and perforative gastroduodenal ulcer

M. Liepins, R. Ribenieks, A. Martinsons and Z. Narbuts
Department of Surgery, Medical Academy of Latvia, Dzirciema Str. 16, LV1007, Riga, Latvia

Introduction: The bleeding and perforated gastroduodenal ulcer is still a significant problem in emergency surgical practice and the incidence of these pathologies has not decreased during the last five years.
Aim: To evaluate the results of treatment in cases of bleeding and perforated gastroduodenal ulcer and demonstrate the main causes.
Material and methods: From 1993–1997 378 patients with a diagnosis of bleeding and perforated gastroduodenal ulcer were admitted to our clinic. Main causes of bleeding and perforation, methods of treatment, complications and mortality were investigated during retrospective research.
Results: 332 (87 per cent) patients with bleeding gastroduodenal ulcer and 46 (13 per cent) with perforated gastroduodenal ulcer were admitted. The majority of patients did not receive adequate conservative medication. In some cases this complication was the first manifestation of ulcer disease. Within the bleeding group (n=332) 133 (40 per cent) of patients were operated on. Within the perforated group we operated on all patients (n=46). In case of perforation 4 (9 per cent) gastric resections, 11 (24 per cent) vagotomies + pyloroplastics and 31 (67 per cent) simple suture procedures were performed. Within the bleeding group, 1 duodenal fistula and two deaths occurred; 96 (72 per cent) operations in the bleeding group were oversewing of the bleeding vessel and 37 (28 per cent) gastric resections.
Conclusions: The most significant treatment for decreasing ulcer disease complications is adequate conservative treatment. An operation may be the method of choice for patients unable to receive the adequate conservative treatment for social reasons.

Secondary mesenteric venous thrombosis due to apparent polycythaemia

E. Marcote, G. Manzanet, R. Adell, A. Torner and M. Canales
Vinaroz Community Hospital, General-Digestive Surgical Service, Vinaroz 12500 Castellón, Spain

Introduction: Mesenteric venous thrombosis is a rare pathological condition due to multiple aetiologies as: inflammatory or infectious conditions, surgical trauma, portal hypertension or hypercoagulability status (such as neoplasia, polycythaemia, contraceptives, thrombocytosis, Antithrombine III deficiency, Protein C or S, or myeloproliferative conditions).
Clinical case: A 27 year old male was admitted with severe, diffuse abdominal pain, vomiting, bloody stools for 48 hours. Exmorbidly obese (he weighed 200 kg and had surgery four years before), heavy smoker (three packs a day). He had, during the last year, four episodes of bloody liquid diarrhoea. He was admitted with polyglobulia (hematocrit 66 per cent, Hgb 21 per cent and Quick 42 per cent). Simple abdominal X-rays shows small bowel dilation, leucocytosis, Hematocrit of 50 per cent and Haemoglobin of 19 gr. At surgery a necrosis of the terminal ileum and caecum was found and a right hemicolectomy was done. He had a good postoperative course. Three months later, determinations of Antithrombin III, Protein C and S, PCA resistance were normal. The erythrocyte mass was normal at 29 ml/kg and so was the Carboxyhaemoglobin of 7·8 per cent. The patient stopped smoking, and is now asymptomatic and has normal hematocrit one year after surgery.
Discussion: The term 'apparent polycythaemia' is applied to a group of patients with elevated hematocrit (over 51 per cent in males and 48 per cent in females) with abnormal erythrocyte mass (below 35 ml/kg in males and 32 ml/kg in females) which is the difference from real polycythaemia. It is common in young males. It is associated with smoking and arterial hypertension and also with obesity, heavy alcohol intake, and diuretic therapy and to hypoxemia.

Burge reports an increase in the incidence of occlusive disease in polycythaemia six times over the expected and Weireb had a high incidence of 30 per cent of thromboembolic complications in these patients. Measured cerebral flow in polycythaemia apparent and vera, has an inverse correlation with the hematocrit. The first step in the treatment is to reverse the risk factors once discovered. If the hematocrit is over 54 per cent, blood drawing and replacement with saline should be done.

Duodenal switch with or without pyloroplasty in the treatment of alkaline reflux gastritis: our experience

G. Pescio, *A. Casano, E. Ramo, F. Bonello, F. Mordeglia and G. Cappuccio *Imperia Hospital, Italy. Division of General Surgery – Chief Surgeon: G. Pescio. *Resident in Postgraduate School of General Surgery – University of Genova, Italy*

Postbulbar total duodenal diversion (PTDD) can be used in the treatment of primary duodenogastric reflux with superior physiologic consequences compared with classic Roux-en-Y.

The procedure consists of a pancreaticobiliary diversion with a small segment of suprapapillary duodenum left in continuity with the stomach to avoid the disruption of the hormonal interplays between duodenal mucosa and gastric compartment in response to acidification of duodenal environment. The suprapapillary duodenum is divided using a TA stapler; a conventional Roux-en-Y is created with minimal dissection of the mesentery to avoid interruption of nerve supply to the bowel. The distal jejunal segment is brought through transverse mesocolon and end-to-end duodenal anastomosis is achieved; end-to-side jejunojejunal anastomosis is carried out at a distance of 50 cm. An extra-mucosal pyloroplasty according to Heinecke-Mikulicz is facultative. The clinical preoperative evaluation of patients consists of: (a) endoscopic demonstration of alkaline gastritis with evidence of bile pooling and pathologic confirmation; (b) 24-hour gastric pH recording; (c) radionuclide 99mTc scanning; (d) radionuclide gastric emptying study or US emptying time evaluation.

We carried out the duodenal switch procedure in 12 patients aged between 26 and 70, all with symptoms of nausea, persistent vomiting and epigastric pain: five had alkaline gastrooesophageal reflux and they underwent PTDD together with antireflux Nissen procedure; one patient had previous Nissen operation without symptoms relief; the remaining six patients were affected with primary alkaline gastritis alone. A pyloroplasty was also performed in two patients to ensure adequate gastric emptying time.

The follow-up (endoscopy with pathologic specimens, barium radiographs, radionuclide gastric emptying study) found the duodenal switch operation of value in the treatment of duodenogastric reflux without inducing delayed gastric emptying if surgical management is entertained in patients selected by accurate preoperative study.

Bronchial carcinoma metastatic to gastrointestinal tract and abdominal wall: report of two cases and review of the literature

L. Santini, G. Conzo, C. Caracò, G. Candela, A. Amore and P. Guadagno *Seconda Università degli Studi di Napoli, Facoltà di Medicina e Chirurgia Istituto di Semeiotica Chirurgica*

Aim: The authors report two rare cases of metastases from bronchial cancer, respectively in a jejunoileal loop, causing intestinal obstruction, and in the right inferior quadrant of the abdominal wall. The aim of the study was the evaluation of the incidence of gastrointestinal metastases from lung carcinoma in the literature, the relative outcome and prognosis. The authors also analyse the role of the surgical treatment and the prognostic factors in these patients.

Material and methods: Two cases of metastases from bronchial carcinoma were observed. In case 1 a jejunoileal obstruction secondary to metastases from lung adenocarcinoma in a male of 69 years, already submitted to radio-chemiotherapy for inoperable adenocarcinoma of the right lung, was observed. The patient underwent jejunoileal resection and right hemicolectomy and recovered fully. In case 2 a large abdominal parietal mass involving the third inferior part of the right rectus muscle in a 64 year old female with undiagnosed squamous cancer of the left lung was observed. Preoperatively it was misdiagnosed as an ovarian neoplasm. The patient was operated on with an explorative laparotomy and resection of the metastasis 'en bloc' with a large part of the inferior right quadrant of the abdominal wall. After the operation the patient underwent six cycles of chemo-radiotherapy for her lung cancer.

Results: The surgical outcome was free of specific complications in each case. Patient 1 died from neoplastic cachexia four months after the operation, while patient 2 is still alive and undergoing scheme of radiochemotherapy, six months after surgery, with partial reduction of the pulmonary mass.

Conclusions: According to the latest reports in the literature, the authors conclude that the metastases of gastrointestinal tract from bronchial cancer are very rare. In every case they represent a terminal compromise of the immune system and so the prognosis is very poor. The appropriate role of surgery is to prevent or to treat the relative complications such as intestinal obstruction or perforation.

High incidence of duodenal ulcer perforation in North-African migrants

P. Soriano Gil-Albarellos, A. Reina Duarte, E. Vidaña Marquez, J. Torres Melero, A. Orte Martinez, E. Alonso Herrera and R. Belda Poujoulet *S° Cirugia General y Aparto Digestivo, Hospital Torrecardenas, Almeria, Spain*

Introduction: We studied the incidence and morbidity-mortality of duodenal ulcer perforation in native Spanish people and in North-African migrants. Peptic ulcer perforation is a stress-related situation in many studies.

Patients and method: Between October 1991 to April 1997, 155 patients were operated on because of peptic ulcer perforation. One hundred and twenty-six were Spanish, 25 North-African migrants, two European tourists, one Chinese cook and one Bulgarian truck-driver. These last four patients were excluded from study. We compared the incidence of perforated ulcer in Spanish and migrant populations, and morbidity factors associated with surgery. The migrants were Group I. We selected all Spanish males under 50 years of age for Group II. Statistical analysis were carried on SPSS and Epitable programs.

Results: Spanish people incidence was 7 cases/100 000 hab. /y., Group I (North-African migrants) incidence was 45·45 cases/100 000 hab. /y and Group II (selected Spanish) incidence was 10·8 cases/100 000 hab. /y. ($P<0{\cdot}001$). Sex distribution was 103 males (81·7 per cent), 23 females (18·3 per cent). All migrant patients were males. Mean age was 47·13 years (13–94), Group I was 30·92±7·85 years, and Group II 32·14±9·7 years ($P=0{\cdot}09$). Mean hospital stage was 11·19±7·5 days, 9·56±5·18 for Group I, and 10·19±8·04 days for Group II ($P=0{\cdot}33$). Peptic antecedents were similar for Group I (52 per cent) and Group II (57·1 per cent; $P=0{\cdot}6$), but other antecedents were higher in Group II (41 per cent) than in Group I (8 per cent; $P=0{\cdot}002$). Surgery was truncal vagotomy plus pyloroplasty 96 per cent in Group I, 91 per cent in Group II ($P=0{\cdot}7$), and 81 per cent for the whole series. Morbidity was 29·36 per cent for the complete series, 12 per cent for Group I and 21·4 per cent for Group II ($P=0{\cdot}39$). Mortality was 5 cases (3·9 per cent).

Conclusions: Peptic ulcer perforation was more frequent in migrant people than in the Spanish population, with statistical significance. Hospital stage and morbidity are comparable between migrants and sex and age related Spanish group. Nutrition, personal, work, social and political situations probably are responsible for the high incidence of peptic ulcer perforations.

Primary and secondary neoplasms of the small bowel and their complications (single centre study)

Gy. Végső, Z. Máthé, M. Tóth, A. Péter, D. Görög and F. Perner *Semmelweis Medical University, Department of Transplantation and Surgery, H-1082, Budapest, Baross u. 23, Hungary*

Introduction: The incidence of small bowel tumours is not accurately defined, the data of different authors showed that they present 0·5–5 per cent of gastrointestinal neoplasms. These tumours are difficult to find by conventional diagnostic procedures.

Aim: to analyse the data of the patients with small bowel tumours during the first four year period of our Institute.

Material and methods: From January 1994 until January 1998 at our department eight patients were treated for small bowel neoplasms. There were six men, average age 46 years and two women, average age 74 years; main hospital stay was 14 days. The following diagnostic investigations were used to find the tumours: abdominal ultrasonography, barium contrast radiography, endoscopy, selective enterography, CT, angiography. The data were analysed retrospectively.

Results: Symptoms associated with the tumours include epigastric discomfort, intermittent abdominal pain, weight loss, palpable abdominal mass, small bowel obstruction and bleeding. The preoperative investigation was successful in five cases. Three of these tumours were found in the jejunum and five of them in the ileum. In three cases acute surgery was necessary because of bleeding and obstruction, in five cases elective operation was performed. Resection of the small bowel was carried out in seven cases, and right hemicolectomy was chosen for oncological reasons in three cases. A malignant tumour of the jejunum was considered not removable surgically, a palliative gastro-enterostomy was performed.

The histological examination showed one leiomyoma, one benign neuromuscular tumour, two malignant carcinoid, one Non-Hodgkin lymphoma, one adenocarcinoma as primary neoplasms and two metastases of malignant melanoma as secondary tumours. On one patient with carcinoid tumour of the ileum – after the resection and chemotherapy– a successful orthotopic liver transplantation was performed because of multiple liver metastases. There were no perioperative complications, we lost two patients (one malignant melanoma, one lymphoma) six months later.

Conclusions: Neoplasms of the small bowel are extremely rare and the symptoms are often vague, the tumours are discovered – in a considerable proportion – too late. Probably for this reason the five year survival rate is about 30–40 per cent. The small bowel tumours always represent a diagnostical and therapeutical challenge for the surgeon.

Anal Canal

A modified Core Out fistulectomy

J.C. Bernal-Sprekelsen, J. López, F. Peiró, *P. Esclapez, A. Alberola, F. Cárdenas and R. Trullenque *Hospital General Universitario de Valencia, Servicio de Cirugía General, Spain. Hospital Clínico Universitario de Valencia (Endoanal US Unit Department of Surgery)*

Aim: To evaluate results of a modified Core Out fistulectomy with a surgical internal sphincter saving dissection and separate layer closure of the sphincters in high and low (in women) transphincteric fistulas.
Patients and methods: Ten patients have been operated on by this technique during the last two years. None had been operated on due to fistula previously. All of them presented with transphincteric fistulas (Park's classification). An incontinence questionnaire (Pescatory scale) was done preoperatively and at three, six months and yearly postoperatively. All patients were prepared the day before surgery with Polyethylenglycol 3–5 l. Surgery was done in lithotomy position in nine cases and endoanal exploration was realized with the Park's retractor. Surgical technique consisted in fistulous tract dissection from the external orifice through the sphincter layers to the internal one. Afterwards a separated layer closure beginning with the internal sphincter was done with absorbable suture. An endorectal mucosa advancement flap was fixed to the internal sphincter in six cases and a vertical simple mucosa suture in four. Wound care was done from the first postoperative day on and weekly postoperative controls until complete healing.
Results: Ten patients (seven male/three female) with a mean age of 38·87 (R: 24–55) were operated on due to anal fistula. The mean wound healing time was between 28–50 days. There were two dehiscences from the advancement flap plasty and two with the vertical suture. None of the endorectal advancement flap dehiscence developed a recurrent fistula. One of the vertical suture dehiscence manifested due to several light rectal bleeding episodes which stopped after spontaneous healing. The other one needed a very superficial sphincterotomy. One case developed a recurrent fistula (10 per cent). Postoperative follow-up was minimum three months and maximum 28 months. Postoperative ultrasound (n=3) revealed images of internal sphincterotomy. No incontinence was seen.
Conclusions: Transphincteric fistulectomy uncutting the internal sphincter allows excision of the fistulous tract in a most preserving sphincter dissection and may be an alternative option in selected cases instead of the classical Seton technique for transphincteric fistulas.

Endoanal ultrasound in evaluation of anal fistula

Costa Pereira and C. Oliveira *Serviço de Cirurgia 3, Hospital de S. João, 4200 Porto, Portugal*

Aim: To evaluate the accuracy of endoanal ultrasound in cases of anal fistula.
Material and methods: We performed endoanal ultrasound to study 38 patients with anal fistula, six of them with recurrent fistula. The patients were in left lateral decubitus position. We used an endorectal ultrasound probe 7·5 MHz, sectoral of 120° with possibility of rotation to 360°, to evaluate the anal sphincters, levator anus muscle, supralevator and ischiorectal spaces and the fistula tracts. We enhanced the fistula tract image by instilation of hydrogen peroxide.
Summary: The diagnoses were: intersphincteric fistula in 20 patients, trans-sphincteric in 10, suprasphincteric in four and subcutaneous in four. The exam was well tolerated and we had a perioperative confirmation of all the ultrasound diagnosis.
Conclusion: Endoanal ultrasound showed to be a well tolerated exam with brief execution and good accuracy in the preoperative classification of fistula tracts, allowing the selection of anaesthesia and surgical procedures.

Efficacy of anal stretch and lateral sphincterotomy in treating children with chronic anal fissures

G. Humphrey, J. Smith and M.D. Stringer *Department of Paediatric Surgery, Gledhow Wing, St. James's University Hospital, Leeds, UK*

Background: A recent study advocated lateral sphincterotomy as treatment of choice for children with chronic anal fissures (Br. J. Surgery 1995; 82: 1341–1342). However, this was disputed in subsequent correspondence (Br. J. Surgery 1996; 83: pages 442 and 571–572). The aim of this study was to evaluate the efficacy of two commonly performed procedures for treatment of chronic anal fissures in children.
Methods: A retrospective analysis of children documented as having a chronic anal fissure treated by anal stretch or lateral sphincterotomy using a surgical log book held by one of the authors (MDS). All procedures were performed by a single surgeon using standard techniques.
Results: Twenty-seven procedures on 21 patients aged between seven months and 9·5 years (18 of 21 less than three years of age) were carried out over a four year period between 1992 and 1996. Twelve of 16 patients undergoing lateral sphincterotomy had healed by eight weeks (including three children who failed to heal following anal stretch) compared with three of 10 patients undergoing anal stretch (11 procedures) $P<0{\cdot}02$.
Conclusions: Lateral sphincterotomy is more effective than anal stretch in treating children with chronic anal fissures. Long-term follow-up studies are required to ensure we are not predisposing these children to faecal incontinence in adult life.

Anal keratoacanthoma – difficult diagnosis, easy therapy: three case reports

J.H.P.M. Jongen, F. Kueppers, M. Reh and J.-U. Bock
Proctological Office and Department of Proctology, Park-Klinik, Goethestrasse 11, 24116 Kiel, Germany

A keratoacanthoma is a rapidly growing tumour, usually occurring on sun exposed areas of the skin. It invades the dermis, but remains local and can resolve spontaneously. Keratoacanthomas, however, are rare in the anal region. To our knowledge only two keratoacanthomas in the anal region are described in the literature. Clinically, but also histologically, this tumour may mimic an anal carcinoma. Three male patients, who were 58, 63 and 64 years of age, presented with a perianal tumour. None of the patients had had a transplantation or were on immunosuppression therapy. Macroscopically the differential diagnosis of an anal carcinoma was made. The tumours were excised. The pathologist could only make the diagnosis of a keratoacanthoma with the additional knowledge of the short history of the tumour (6–10 weeks). The history, clinical appearance, therapy, pathology, follow-up and prognosis of these patients with this rare anal tumour are demonstrated. After securing the diagnosis no further therapy for the anal keratoacanthoma is needed.

Anal endosonography is a useful diagnostic tool in anal fistulas and anal abscesses

R. Leppert, M. Kraemer, M. Sailer, D. Bussen, K.H. Fuchs and A. Thiede *Department of Surgery, University of Würzburg, Josef-Schneider-Str. 2, D-97080 Würzburg, Germany*

Anorectal endosonography is a new technique, which permits preoperative diagnosis and classification of anorectal abscesses and fistulas. With instillation of hydrogen peroxide blind ending fistula tracks and complex fistula systems may be visualized. The correct anatomical classification of fistulas and abscesses in relation to the anal sphincter may be decisive for the operative treatment. Until recently, the exact course of an anal fistula could be demonstrated only at operation by laying open the fistulous tract. X-ray contrast studies gave only evidence of possible fistulous side tracts and extensions into the rectum without representing their relation to the sphincter system. With anal endosonography it is possible to directly visualize the lesions caused by fistulas and abscesses in relation to the anal sphincter muscles. We want to report our endosonographic experiences with 81 patients with anal fistulas and/or abscesses. In 89 per cent of the fistulas and 100 per cent of the abscesses a correct preoperative diagnosis according to the Park's classification was made by endosonography. Anal endosonography therefore is a suitable and helpful diagnostic tool in the diagnosis of anal fistulas and abscesses, non-invasive, easy to perform and relatively inexpensive.

Results of surgical treatment for differentiated thyroid carcinoma

D. Bordos, C. Caloghera and M. Miclaus *II-nd Surgical Clinic, University of Medicine and Pharmacy Timisoara, Romania, str. Liviu Rebreanu 156 cod 1900*

Aim: To evaluate the early and late results of our therapeutic approach in patients with differentiated thyroid carcinoma, which is strongly related to the stage of the disease and to the risk group of the patients.
Material and methods: Records of 134 unselected patients with differentiated thyroid carcinoma operated from 1971 to 1997 were retrospectively analysed. The histologic type of carcinoma was: folicular in 46 patients (34·33 per cent of cases), papiary in 45 patients (33·58 per cent of cases) and mixed papillary and folicular in 43 patients (32·09 per cent of cases). In the low risk group (AMES criteria) there was 88 patients (65·6 per cent of cases): near total lobectomy on the side of the lesion and subtotal lobectomy on the contralateral side was done. The high risk group includes 46 patients (34·33 per cent of cases); total lobectomy on the side of tumour and contralateral subtotal or near total lobectomy was the operation of choice. Thyroid suppression and radioactive iodine were added. The postoperative morbidity rate was 23·88 per cent (32 patients) and the postoperative mortality rate was 3·73 per cent (five patients). The 10 year survival rate was 95·45 per cent (84 cases) in the low risk group of patients and 62·79 per cent (27 cases) in the high risk group. The recurrence rate of the disease was 6·72 per cent (nine patients). The tumoral antigenic markers were evaluated periodically; also sonographical assessments of the remaining thyroid was done.
Conclusion: These data indicate that this quite conservative surgical approach used at our institution has similar results to more extensive surgical treatment used in other institutions.

Our experience in aesthetic rhinoplasty: study made on 500 operated cases

Al.V. Georgescu, C. Major, O. Ivan and R. Onoe *Clinic of Plastic Reconstructive Surgery, University of Medicine 'Iuliu Hatieganu', Spitalul Clinic de Recuperare, 3400 Cluj-Napoca, Str. Viilor Nr. 46–50, Romania*

Introduction: The nose plays a very important role in defining one's facial aspect and this was – beside its central position on the face – the main reason for Lavater to call it 'the keystone of the face'. The shape of the nose does also involve some character features. These would be just a few of the reasons confirming the necessity of performing rhinoplasty.
Material and methods: Here is presented a retrospective view of the 500 operated patients in seven years – 435 females and 65 males. The age of the patients varied within the limits of 16 and 47 years. In 355 of the cases we were confronted with constitutional deformities, the other 145 being performed on post-traumatic or postoperative deformities.

In all the operated cases, the surgeon had to consider patients' motivation, considered as sufficient and real when it showed up as the result of a long duration acknowledgement of the defect by the patients, involving psychological and character problems.

In order for the best aspect to be achieved it has to be performed in the preoperative stage (for the great majority of the patients) a photographic or computer based analysis of the potential result, ending in choosing – with the patient's consent – the best variant.

Technically, in 472 cases it was performed a closed rhinoplasty, the open rhinoplasty being chosen only for a few post-traumatic deformities. In 15 of the cases a silastic prostheses was used.
Results: In appreciating the results we mainly took into account the patient's degree of satisfaction with them. And so for 400 of the patients (80 per cent) the result was a very satisfactory one, for the other 100 (20 per cent) it was just good. From these 100 patients, 28 of them (5·6 per cent) needed further surgery.
Conclusions: 1. Any aesthetic surgery intervention's guiding line is to make the patient look better; 2. The aesthetic surgery of the nose helps the patient in his instinctive need for correcting existing deformities; 3. The estimation of the result by the use of photographic methods and computer software substantially increases the intervention's rate of success.

Three dimensional CT-reconstruction in patients with atlanto-axial rotary fixation

M. Haakonsen, T.E. Gudmundsen and O. Histöl *Department of Radiology and Orthopaedics, Central Hospital of Buskerud, N 3004 Drammen, Norway*

Aim: Patients with suspected atlanto-axial rotary fixation are in some instances difficult to diagnose properly without using computed tomography. In our hospital three dimensional reconstruction of CT examinations have been used routinely when evaluating such patients thereby obtaining valuable diagnostic information. The aim of our presentation is to describe the method used and how it may be applied.
Material and methods: We present a ten year old girl who suffered a neck trauma when hitting the bottom of a swimming pool while diving. Severe neck pain occurred immediately. After a short period of time her neck became 'stiff', rotated and fixed in flexion. Clinical examination and conventional radiograms were inconclusive, but fracture was suspected. Standard CT examination did not offer any conclusion, but spatial CT with three dimensional reconstruction revealed an atlanto-axial rotary fixation.

The examinations were performed using a Phillips Tomoscan SR 7000. Field of view (FOV) was set to 110 using 250 mAs and 120 kV. For the reconstruction FOV was adjusted to area of interests and the reconstruction index was set to 1 mm.
Conclusion: A proper treatment of atlanto-axial rotary fixation requires an exact and early diagnosis. As both clinical, conventional radiographic and standard CT examinations may be inconclusive, we strongly recommend to examine these patients with three dimensional CT-reconstruction to obtain a best possible graphic picture of the anatomic conditions.

Chemodectomas diagnosis and localization: advantages of 111In-pentetreotide over 123I-MIBG scintigraphy

M.A. Muros, M.A. Arráez, J.M. Llamas, E. Valencia, A. Ramírez, M. Gómez-Rio and R. Vílchez *Department of Nuclear Medicine, Avda. Fuerzas Armadas 2, Hospital Virgen de las Nieves, 18014 Granada, Spain*

Aim: Chemodectomas or Glomus tumours are unusual head and neck paragangliomas. The non-invasive imaging technique metaiodobenzylguanidine (MIBG) scintigraphy has been used for the diagnosis of all types of paragangliomas during years. The purpose of this study is to evaluate and to compare the classic 123I-MIBG scintigraphy and the recent 111In-pentetreotide scintigraphy in the diagnosis and localization of chemodectomas or glomus tumours.
Material and Methods: In order to get it, we have performed 123I-MIBG and 111In-pentetrotide scintigraphy in eight patients (seven women and one man) with histologic or radiologic confirmation of chemodectoma (five carotid body and three yugolotympanic chemodectomas).
Results: 123I-MIBG uptake were visualized in four patients on planar views and SPECT images (sensitivity 50 per cent, 4/8), and uptake was low to moderate in all patients. Using 111In-pentetreotide scintigraphy all chemodectomas of our eight patients were visualized (sensitivity 100 per cent, 8/8), and 111-In-pentetreotide uptake intensity was high in all cases.
Conclusions: In conclusion, this study indicates that 111In-pentetreotide scintigraphy is superior to 123I-MIBG scintigraphy in diagnosis and localization of chemodectomas or Glomus tumours. Moreover, 111In-pentetreotide scintigraphy permits a good classification of patients with or without somatostatin receptors in the chemodectoma in order to intend a pharmacological therapy with somatostatin analogues in inoperable tumours.

Programme of major surgery with minimal hospital stay: assessment after one year under development

F. Docobo, M.A. Prieto, M. Fernandez, J.L. Blanco, H. Amoudi, A. Galindo and A. Razak *St. Camilo Jose Cela, Manzana 1-Bloque 8-3^{0}A, 41018 Sevilla, Spain*

Aim: Surgery involving the minimal hospital stay offers evident advantages to the patient and hospital. The results obtained in a programme of major surgery in which the hospital stay was 24 hours or less are presented after one year of development.

Material and methods: Between January to December 1997 a total of 4806 patients were operated in our hospital. Fifty-two vascular procedures, 210 urological, gynecological 6, ophthalmic 870, ear nose and throat 735, general surgery 876, procedures and minor procedures 2057.

The basis of our programme involved those patients with a requirement of about 24 hours hospitalization or less (F.E. laparoscopy in biliar pathology).

Results: In relation with our admission criteria a high percentage of our patients were out in the same day. 4115 patients (85·58 per cent) were out the same day and 691 (14·32 per cent) stayed more than 24 hours, in general for minor complications (pain, general disorders, etc) or geographical factors. No problems were observed in patients review in gynecological procedures, four arterio-venous fistula were occluded and needed a second operation. Ophthalmic patients (cataract mostly) were out in the same day with no problems. ENT patients required hospital stay, 35 cases for bleeding. In general surgery most of patients were operated on in the afternoon and were out at the following day in the morning with less than 24 hours stay. We observed five recurrences in groin hernia operated on without protheses.

Conclusion: We consider that AM surgery in our unit has improved quality of life.

Advantages of one day surgery in proctological practice

P. Labaš, B. Ohrádka, L. Vrtík and J. Sekáč *1st Department of Surgery, Faculty Hospital Mickiewiczova 13, 813 69 Bratislava, Slovakia*

In the last seven years the authors have safely operated on 640 patients in the out-patients department, all for proctological diseases under local, regional and caudal peridural anesthesia. These included 396 haemorrhoidectomies (Morgan-Milligan procedure), 25 lateral internal sphincterotomies and 88 anal stretches for fissures, 56 transsphincteric fistulas (silk thread, elastic ligatures), 45 ischiorectal abscesses (drainage, silk thread), 32 rectal prolapses (Delorme-Rehm + Tiersch plastic with wire). After observation, 5·3±0·5 hours, on the same day patients were discharged home, but a surgeon was on call. Only 4·4 per cent, 25, of operated patients had some problems in the first 24 hours, bleeding, pain, discharge, retention of urine. All patients were checked after 3, 7 and 14 days. 79·5 per cent from 452 patients were operated under caudal peridural anestesia, 20cc of 0·5 perc. Marcain, with optimum and satisfactory analgesia, the rest under local infiltration Lidocaine 0·5 perc. and Adrenaline 1:200000. Postoperative pain was reduced with long acting analgesia combined with non steroid anti-inflammatory drugs with excellent results.

Most proctological diseases can be operated on and treated as one day surgery cases under safe and effective caudal peridural anaestesia which gives a guarantee of 5 to 8 painless postoperative hours. The reduction of the hospital stay of patients treated surgically for proctology is an attractive alternative that lowers cost without increasing morbidity.

Aesthetic one day surgery

M. Trybus, J. Trybus and I. Olszewska *2nd Department of Surgery of the Jagiellonian University, Kraków, Kopernika 21, Poland*

The presented materials includes 228 patients operated on for aesthetic purposes only in the outpatient clinic of plastic surgery within the years 1993 to 1997. One day surgery is preferred there, on account of considerably reduced total costs of treatment. The age of the patients ranged from 5 to 68 years.

The most frequent indications were nonaesthetic scars (63 patients – 27·6 per cent). The other were: prominent ears (60 patients – 26·3 per cent), nasal deformities (36 patients – 15·7 per cent), different kinds of mammaplastics (24 patients – 10·5 per cent).

Most patients were operated on under local anaesthesia (143 patients – 62·7 per cent). General anaesthesia was delivered in more extending surgical procedures and in children.

The majority of patients were treated in the ambulatory setting. Those, who underwent operation under general anaesthesia were usually discharged home two hours after operation. Only a few of them (11 patients – 4·8 per cent) were admitted for two or three days. It depended on the extent of operation procedure. All these patients received antibiotics i.v. in bolus at the beginning of the operation. In some cases of PONV (postoperative nausea and vomiting) Zofran 4 mg i.v. was administered in single dose.

In general, the complication rate was rather low and did not exceed 4 per cent of cases. According to the simple scale worked out by us a few years ago, we have obtained more than 90 per cent of very good and good results.

In our opinion, existence of one day surgery depends on good organisation and cooperation between surgeon and anaesthetist.

Major ambulatory surgery: organization and results after one year of experience

M. Vilches Martínez, D. Huerga Alvarez and A. Payno de Orive *Fundación Jimenez Diaz, Clínica de la Concepción, Avda. Reyes Católicos 2, 28040-Madrid, Spain*

The creation of Units of Major Ambulatory Surgery has become necessary to compensate the increased number of surgical patients in waiting lists and to reduce costs without decreasing the quality of the assistance. In this study we analysed the structure, arrangement and results of our Department of Major Ambulatory Surgery after one year of experience. A total of 2241 surgical procedures was performed by the different specialities: Ophthalmology 980, General and Digestive Surgery 393 (Proctology and Abdominal wall), Otorhinolaryngology 384, Orthopedic Surgery 38, Gynecology 69, Plastic Surgery 286, Urology 52, Stomatology 21, Others 5. The mean duration of the procedures was 54 minutes and the mean time needed for recovery oscilated from 10 to 49 minutes. Retobulbar anesthesia was used in 960 cases, general in 754, local with sedation in 270, and subarachnoidal in 93. There was a minimum percentage of epidural anesthesias and local anesthesia was used in the rest of cases. The rate of complications was very low, with 2 per cent of admissions, 0 per cent of readmissions, 3 per cent of emergency aids and 4 per cent of telephone calls. The degree of patient satisfaction was very good in 55 per cent of cases and good in 35 per cent.

Conclusions: Major Ambulatory Surgery performed in Units specially designed for it is a fast and viable method in our system. We think that this constitutes the method of choice for the surgical treatment of a great variety of pathologies due to its low cost, few complications and the high level of participation of the different surgical specialities as well as the great patient acceptance.

Day surgery anaesthesia

B. Zanella, P. Gazzani, S. Magagnotto and G. Aguzzi *Anestesia Rianimazione, Ospedale Legnago Via Gianella, 1 37045 Legnago (Verona), Italy*

In the USA more than 50 per cent of the surgery interventions are thought to be feasible in Day Hospital. In Italy ambulatory surgery is undergoing an important development owing to the introduction of surgery methods less and less invasive and to the adoption of Local Regional Anaesthesia (LRA) as alternative to the General Anaesthesia (GA).

Advantages of LRA: 1. Patient quick autonomy; 2. Nausea and vomiting absence; 3. Satisfying analgesia in the post-intervention; 4. Early nourishment. Disadvantages: 1. Headache; 2. Retention of urine; 3. Orthostatic hypotension. In our DH-Department the following interventions have been carried out: nr. 330 in Superselective Spinal Anaesthesia (SSA), nr. 24 in Plexis Anaesthesia (PA), nr. 170 in Local Anaesthesia + Sedation (LA+S).

All the patients are classified as ASA 1 and ASA 2, aged between 16 and 82 years old, average 42. During the intervention the PA, ECG, and SaO2 are monitored. The SSA has been adopted for varix surgery and for athroscopy, being a less traumatic method and for the scanty hemodynamic pertubation involved, considering the limited extension of the sympathetic block. For nerve isolation the neurostimulator is employed to help to block the brachial plexus. In inguinal hernia surgery the LA+S has been adopted, using Xylocaine and Midazolam. During the interventions in case of hypotension over 20 per cent of the base value, reduced quantities of α stimulating drugs are given, avoiding filling. In one case in LA+S a severe crisis of broncho-spasm occurred, which was resolved by using broncho-dilatators and O2.

Adopted criterions for discharge: 1. Full restoration of the conscience after sedation; 2. Nausea and vomiting absence; 3. Spontaneous return of diuresis; 4. Absence of sympathetic blockage. All the patients are dismissed within four hours of the intervention. During the checking in the sixth day no one patient reported complications connected to the anaesthesiology method. The LA is the most suitable method for the ambulatory surgery because it allows for a rapid dismissal with scanty or null complications.

Extra-corporeal methods of detoxification and immunomodulation in the management of acute purulent mediastinitis

D.Y. Artioukh and A.L. Akopov *State Research Centre of Pulmonology, 12 Röentgen St., St. Petersburg, 197089, Russia*

Aim: Acute purulent mediastinitis is characterized by significant endotoxaemia and often associated with immune deficiency, necessitating an adjuvant treatment aimed at detoxification and immunomodulation. The purpose of the study was to compare the detoxification and immunomodulating effects of four different methods: haemoperfusion (HP), plasmaphoresis (PS), extra corporeal irradiation of autologous blood with laser (LI) and ultraviolet light (UVI) in the treatment of this inflammatory condition.
Material and methods: 31 patients (19 men, 12 women; median age 43 years, range 17 to 61 years) suffering with acute purulent mediastinitis of various aetiology were divided into four groups according to the employed method of detoxification and immunomodulation: HP (7 patients), EP (8 patients), LI (8 patients) and UVI (8 patients). All procedures were carried out only after surgical drainage of the primary focus of inflammation. Effects were assessed before and on the first day after the procedure by measuring the level of endotoxaemia (serum mean molecular weight peptides), certain parameters of antibody (serum Ig A, G, M) and cell-mediated immunity (T lymphocyte and active T lymphocyte count) and phagocytic activity of neutrophils and monocytes.
Results: HP had the maximum detoxificating effect, slightly stimulated antibody-mediated immunity but suppressed cell-mediated immunity and phagocytosis. PS also had the detoxificating effect, though inferior to that of HP, and caused deterioration of all measured immunological parameters. Both LI and UVI had no detoxification properties but stimulated antibody and cell-mediated immunity and phagocytosis. The immunomodulating effect of LI was found to be superior to that of UVI.
Conclusion: HP and PS could achieve effective detoxification but had the undesirable side-effect of immunosuppression. Conversely, LI and UVI did not influence the existing endotoxaemia but showed the immunostimulating effect. In order to overcome the side-effect of HP and PS, it might be beneficial to use these methods in combination with LI and/or UVI.

Efficacy of Piperacillin/Tazobactam in intra-abdominal infections

A. Cane Matias, A. Perez Sanchez, R. Pérez Huertas,
D. Candil Comesaña, F. Cuaresma Soriamo, J. Alvarez Galan and
D. Martinez Obradó *Department of Surgery II, Virgen
Macarena Hospital, Avenida Doctor Fedriani no. 3, 41071,
Seville, Spain*

Introduction: Most intra-abdominal infections are usually polymicrobial. The treatment requires surgical intervention together with antibiotic therapy against aerobes and anaerobes. Piperacillin is a potent antimicrobial proven to be active against a broad range of gram-negative pathogens. The combination with Tazobactam (potent betalactamasa inhibitor) is particularly promising for use in these infections.
Aim: To compare the safety and the clinical-microbiological efficacy of Piperacillin/Tazobactam vs Cefotaxima plus metronidazole in intra-abdominal infections.
Material and methods: Eighty adult patients with documented intra-abdominal infections for peritonitis, intra-abdominal abscess, complicated appendicitis or diverticulitis and cholecystitis requiring laparotomy were enrolled. Forty patients were treated with Piperacillin 4 g/Tazobactam 500 mg every 8 hours and 40 patients with cefotaxima 1 g plus metronidazole 500 mg every 8 hours. We compared clinical and bacteriological efficacy, tolerance and adverse effects.
Results: A 95 per cent (38/40) favourable response (cured/improved) was demonstrated in the group treatment with Piperacillin/Tazobactam and 82 per cent (33/40) with cefotaxima plus metronidazole. The eradication rate in patients at early and late follow-up evaluation was 90 per cent with Piperacillin/Tazobactam and 88 per cent with the second group. The incidence of adverse effects in the group treated with Piperacillin/Tazobactam was five patients (12·5 per cent) and seven patients (17·5 per cent) in the other group. The rest of parameters were not significantly different.
Conclusions: Results of the present study show that Piperacillin/Tazobactam is effective for monotherapy of intra-abdominal infections and it represents a safe alternative as empirical therapy in peritonitis.

Postsurgical infections in bariatric surgery using gastric bandage

*S.B. Doldi, †G.C. Micheletto, †M.A. Zappa and †R. Germiniani
First Chair of Surgery, S. Ambrogio Hospital, Milan, †Institute of General and Oncologic Surgery, University of Milan, Policlinico Hospital, Milan, Italy

Postsurgical infection (PI) rates have been clearly reduced by adopting laparoscopic procedures. In open bariatric surgery postoperative complications such as surgical wound infections or respiratory (RTI) and/or urinary tract infections (UTI), were quite frequent. Moreover, the obesity is an outstanding risk factor that significantly increases the postsurgical infection rates in most surgical procedures. Laparoscopic surgery, minimizing the length of surgical incision and allowing an earlier postoperative mobilization of the patient, would play a favourable role in decreasing postoperative complications also in bariatric surgery. A brief analysis of our data is reported here, regarding 49 consecutive patients in which a laparoscopic gastric bandage was carried out in the last three years.
Material and methods: From March 1995 to December 1997 49 obese patients were submitted to laparoscopic adjustable gastric banding, as firstly described by Kuzmack (1990). Among them 15 were males (30 per cent) and 34 were females (70 per cent). The mean age was 37 years (SD 9), ranging from 18 to 60 years. The mean preoperative BMI was 46·3±5·4. In five patients laparoscopic procedure was converted to open procedure (10 per cent). The mean surgical time was 120 minutes, ranging from 90 to 180 minutes. In open procedures it was of 150 minutes and in laparoscopic procedure it was of 120 minutes. Perioperative antibiotic prophylaxis was adopted in every patient, using a long acting cephalosporin (Ceftriaxone). The mean length of postoperative hospitalization was five days, ranging from four to seven days. In the early postoperative period only two PI were recorded: one SWI recorded and one RTI. Neither intra-abdominal nor UTI were observed. The mean follow-up was 19 months and no late postsurgical complications were detected or referred by the patients.
Conclusions: A PI rate of 4 per cent compares favourably to our previous experience in open surgery: seven (14 per cent) PI were scored in 51 patients submitted to gastric bandage and 23 PI (16 per cent) were detected in 146 patients submitted to gastric bypass. It seems reasonable to confirm laparoscopic gastric bandage should be considered as gold standard for surgical treatment of the morbid obesity, in suitable patients.

Specificity of catheter related bacteremias (CRB) development in intensive care units with surgical profile

V. Edreva, K. Pavlova, L. Beshev and M. Sredkova *Department of Microbiology, University School of Medicine-Pleven 1, Kliment Ohridsky St., 5800 Pleven, Bulgaria*

Objective: To study the specific features in development of catheter related bacteremias (CRB) in Intensive Care Units (ICU) with surgical profile at the ICU and Nephrology Clinic of the University Hospital Pleven.
Patients and methods: Fifty-two patients with clean surgical operations and central venous catheters used for total parenteral nutrition and drug admission and 52 patients with central venous catheters used for haemodialysis (control group). Microbiological study of the skin on inser-

tion site before disinfection; semiquantitative and quantitative analysis at 2 cm from the catheter tip using methods of Maki and Cleri; blood cultures obtained from the peripheral vein.

Results: Mean duration of catheterization for experimental and control groups was 10 days and 22·8 days, respectively. Skin colonization was observed in 23 cases and 36 cases, respectively. Catheter colonization was found in 32 and 26 cases, respectively. The most frequently isolated microorganisms at ICU patients were Gram negative rods – in 21 cases (65·6 per cent), followed by Coagulase negative staphylococcus – 10 cases (31·25 per cent). Coagulase negative staphylococcus – in 19 (73·07 per cent) cases, followed by S. aureus – four cases (15·8 per cent) were isolated at the control patients.

CRB were proved in 11 experimental cases (21·1 per cent) and five control group cases (9·6 per cent). Six out of all CRB in ICU were developed after catheter had been used more than seven days, four CRB – more than 14 days and one CRB – more than 21 days. CRB in the control group had been developed after catheter use more than 14 days. The most frequently observed CRB agents in ICU were Gram negative rods – nine cases (81·8 per cent), and at control group – Staphylococcus – three cases (60·0 per cent).

Conclusions: Frequency of CRB is significantly higher in surgical ICUs compared to other low risk units. CRB is earlier developed and Gram negative rods are the dominating microorganisms. Catheter hub, and not the skin, is the most probable way for CRB.

The present surgical infection: aetiology and optimization of therapy

I. Geritch, A. Barwinska and Yu. Kushta *Lviv Medical University, Ukraine 290008 Lviv, Barwinsky St. 5/1*

Aim: To study the aetiology of present surgical infection and examine their sensitivity to antibiotics. We analysed results of conventional bacteriological investigations during 1995–1997 of 478 cases, in which 424 aerobically bacteria colonized.

Results: From 424 cases were microbial colonia in monocultura 403 (95 per cent) and in association – 21 (5 per cent). Gram-negative bacteria dominated – 277 (65·3 per cent), in most cases – enterobacteria (187; 67·9 per cent). The typical association (13; 61·9 per cent) included Gram-positive microbe (Staphylococcus or Streptococcus) and enterobacteria. It calls one's attention on high percentage of saprophytes or conditionally pathogenic microbe – Staphylococcus epidermidis (44; 10·4 per cent) and Proteus (89; 20·9 per cent).

Generally, in microbial spectrum of present surgical infection during period 1995–1997 raised percentage of Gram-negative flora (χ^2=6·1; P<0·02). They have high level of antibiotic resistance with a tendency to increase every year.

Conclusions: 1. Today the aetiology of surgical infection is dominated by Gram-negative flora: E. Coli (18·8 per cent), Enterobacter (12·3 per cent), Citrobacter (12·3 per cent), Klebsiella (9·4 per cent), Pseudomonas (9·0 per cent) and Proteus (32·1 per cent). They have critically high levels of antibiotic resistance which increases every year. 2. In every third case the causes of surgical infection are new pathogenes (St. epidermidis and Proteus); they are typically seen in people who are immunosuppressed. 3. The initial antibioticotherapy should base on apriorally using medicine, which are effective against Gram-negative flora. Conventional antibiotics (penicillin, tetracycline and others) must exclude from present arsenal of surgical infection therapy. 4. In context of fast increasing of microbes' antibiotic resistance the tactics of present therapy of surgical infection should be corrected on base of multicentral bacteriological investigation results.

Successful conservative treatment of an infected thoracic aortic graft

T. Hüttl, I. Repa, Z. Szabolcs and K. Hüttl *SOTE, Department of Cardiovascular Surgery, Városmajor u. 68, Budapest, H-1122, Hungary*

According to general surgical experience implanted infectious material must be removed. In cardiac surgery this especially is the case. In our situation conservative treatment resulted in definitive recovery.

A middle-aged woman was seen in our department because of chest pain. The detailed examination showed preliminary deBakey type III, dissection of the aorta with aneurysm formation in the chest. Using extracorporeal circulation a 30 mm sized Haemoshield graft was implanted into the sack of the aneurysm and its wall was wrapped loosely around the graft to achieve proper haemostasis. The first postoperative days were uneventful, but 10 days after the operation when the patient had been transferred to another hospital her temperature and leukocyte count was found to be elevated. Two weeks later the lady was admitted again with high fever and poor overall condition. CT showed liquid collar around the graft that turned out to be pus. We planned to replace the graft with a homograft aorta, and as a temporary solution a side and end hole catheter was guided into the cavity with CT control. Continuous sucking and rinsing with antiseptic solution was carried out accompanied by parenteral antibiotic treatment. In two weeks the patient's complaints and clinical symptoms discontinued, CT showed nearly complete regression. The catheter was removed and further antibiotic therapy was continued. A month later the disease was cured clinically and radiologically.

Infectious complications of decubitus ulcers

P. Metrikas and V. Biskys *Rehabilitation Hospital of Palanga, Vytauto str. 153, LT-5720 Palanga, Lithuania*

Our experience showed that the open wound of a pressure sore is always contaminated with bacteria. Staphylococcus aureus, E. coli, Pseudomonas aeruginosa are more frequently identified with decubitus ulcers. This is most important for developing of the different infectious complications to patients with decubitus ulcers. These are such as phlegmonously inflamed pressure sore, infected subcutaneous necrosis of fatty tissue, inflamed bursa, osteomyelitis, sepsis. Sepsis resulting from these conditions can be life-threatening.

This study was based on 34 patients suffering with 66 IV-V stages decubitus ulcers from September 1994 to December 1997. Each patient had a full clinical examination, blood and urine laboratory study, bacteriological studies of the ulcer, blood and urine and X-ray studies. The results of the studies showed: (1) all of the patients had phlegmonously inflamed pressure sore, infected subcutaneous necrosis of fatty tissue or inflamed bursa; (2) osteomyelitis was diagnosed in 23 patients and (3) five patients had sepsis. The treatment of the first group consisted of applying a disinfectant dressing 2–3 times a day. Antibiotic therapy and emergency debridement was applied to 28 patients. The kind of antibiotic depends on results of the culture. If osteomyelitis was diagnosed resection of the infected bone was performed. The septic patients needed the most serious treatment. It consisted of earlier enumerated, a high concentration of antibiotics, detoxication therapy. One patient had a purulent pressure sore on the greater trochanter, V stage, coxitis and sepsis, was moved to a higher level of the hospital, where he died. All of the other patients recovered. The final step-plastic surgery of decubitus was performed after 6–8 weeks when ulcers became 'clean'.

Cytomegalovirus infections of the foregut in renal transplant recipients: diagnosis and treatment

G. Morris-Stiff, D. Bowrey, B. Shrestha, R. Moore, R. Lord and A. Jurewicz *Department of Transplant Surgery, University Hospital of Wales, Cardiff*

Aims: Cytomegalovirus (CMV) is the commonest infective agent in transplant recipients after the first postoperative month with the incidence of infection approaching 40 per cent. The incidence of gastrointestinal CMV disease is only 2 per cent, however, mortality is considerable if the infection is unrecognized and untreated.

Methods: We reviewed the notes of all patients undergoing transplantation at our institute between June 1989 and May 1997 to determine the incidence and outcome of CMV disease affecting the foregut.

Results: In this eight year period 610 patients underwent transplantation of which 595 received kidney alone and 15 received combined pancreas/

kidney grafts. Seventy-four patients (12 per cent) were treated for CMV disease of which 11 (1·8 per cent) had primary upper gastrointestinal CMV. Eight of the patients were CMV –ve preoperatively and received CMV +ve kidneys, two cases were CMV –ve to CMV –ve and one CMV +ve recipient received a CMV –ve kidney. All patients reported epigastric pain/dysphagia, 9/11 were pyrexial and 9/11 were leucopaenic. The CMV antigenaemia assay was performed on a buffy coat preparation for the detection of CMV late antigen (pp65). All patients underwent endoscopy with mucosal biopsies taken and stained with haematoxylin and eosin, diagnosis being confirmed by the identification of CMV inclusion bodies (Owl's eye appearance). All patients were treated with intravenous gancyclovir for a median of 21 days (10–21 days). Four of the patients relapsed and required further treatment with gancyclovir.

Conclusion: Upper gastrointestinal tract infection with CMV is a rare but important cause of morbidity in the post-transplant period. A suspicion of CMV in patients with fever and dysphagia, followed by rapid diagnosis and treatment has led to a dramatic improvement in the outlook for this condition.

Muscular hydatid disease: a rare infection

M.J. Palacios, A. Güemes, J.M. Ramírez, F. Burdío, J. Torcal, E. Tejero and R. Lozano *Servicio de Cirugía 'A', Hospital Clínico Universitario, Zaragoza, San Juan Bosco, s/n 50009, Zaragoza, Spain*

Introduction: Primary muscular hydatid cysts are rarely seen even in endemic populations, corresponding to less than 1–5 per cent of the whole location. These cysts appear as a rapidly growing mass of soft tissue, sometimes with inflammatory signs and fistulization. This tumour must be differentiated from soft tissue neoplasm. MNR is the most accurate exam used to make such distinction. Ultrasonography and CT scan have less accuracy. The patients usually require several operations to eradicate the cysts.

Aim: This is a retrospective study of the hydatid disease affecting the muscle.

Patients and methods: Between January 1990 and December 1997 six patients underwent surgery for muscular hydatid cyst. We reviewed only primary muscular cyst located initially in the muscle. We have analysed age, sex, location, symptoms, diagnostic procedures, surgery, local relapse, and present status.

Results:

	Age	Sex	Location	Symptoms	Diagnostic	Surgery	Status
Case 1	53	F	Back	Mass	MNR	Curettage	Healthy
Case 2	56	F	Limb	Mass	MNR	Curettage	Healthy
Case 3	64	F	Limb	Mass	MNR	Compartment resection	Healthy
Case 4	70	M	Diaphragm	Vomica	CT	C+PC	Healthy
Case 5	46	M	Back	Mass	MNR	C+PC	Relapse
Case 6	60	M	Back	Mass	MNR	C+PC	Healthy

C: cystectomy; PC: pericystectomy.

Conclusions: In the differential diagnosis of growing mass of the back and extremities we must keep in mind the rare cases of hydatid cysts of muscular origin. This benign condition is easily diagnosed in CT scan or MNR exams. Fine needle biopsy (FNB) is not indicated in the cases of suspicion of hydatid disease because increase risk of infection and fistulization. Total removal of the cyst including the pericyst performed using the same techniques used in treating the hepatic or pulmonary affection.

Neutropenic enterocolitis in patients without leukemia

M. Salvador-Fernández, J. Martín-Benito, J. Vazquez-Echarri, J. Ruiperez, J. Escudero, D. Lacasa and J.L. Martínez-Veiga
Servicio Cirugía General y Digestiva, Hospital Insalud 'Severo Ochoa', Ada Orellana s/n, Leganes 28911, Madrid, Spain

Aim: The aim of the present study is to report two cases of nonleukemic neutropenic enterocolitis and review the literature.

Introduction: Neutropenic enterocolitis is a clinicopathological condition characterized by a septic or inflammatory intra-abdominal process in patients with haematological malignancy or who are neutropenic for a variety of other reasons. With the greater use of aggressive multiagent antineoplastic chemotherapy the condition is increasingly recognized. The aetiology, pathogenesis and optimal clinical management remain unclear.

Material and methods: This is a report of two cases of nonleukemic neutropenic enterocolitis in a patient after the administration of chemotherapy for lung carcinoma and in a patient with multiple myeloma. In addition to the report a medline search was carried out and all relevant papers were reviewed. Information sought included the patient's age, sex, underlying disease, clinical presentation, laboratory findings, the type of treatment and outcome.

Results: There were 37 patients. Age ranged from 6 months to 74 years. There were 21 men and 16 women. The underlying disease diagnoses were aplastic anemia in eight patients, solid tumour in 12, multiple myeloma in four, drug-induced agranulocytosis in four, polymyositis one, bone marrow transplantation one, human immunodeficiency virus infection three, cyclic neutropenia two, and in two patients no cause was found. Most patients presented abdominal pain, diarrhoea and fever, with 16 of them showing signs of peritoneal irritation. The treatment was surgical in 19 patients and non-surgical in 12, with no information available in six. Most patients operated were due to the suspicion of a perforated viscus. The outcome was recovery in 10 patients in the surgical group and seven in the non-surgical group, nine patients died in the surgical group, meanwhile six died in the non-surgical group.

Conclusions: With the greater use of aggressive chemotherapy is likely to be encountered more frequently. No obvious superiority of medical or surgical treatment. In patients who need surgery, neutropenia should not be a contraindication.

Laparotomy in treatment of intraabdominal abscesses

M. Śmietański, M.I. Pirski, M. Łukiański and T. Draczkowski
I Department of Surgery, Medical University of Gdańsk, Debinki 7, 80-211, Gdańsk

Aim: Evaluation of repeated laparotomy in selected cases of intraabdominal abscesses.

Material and methods: During the years 1992–1997, 34 patients with large intraabdominal abscesses were treated by repeated laparotomy. The causes of intraabdominal abscesses were: complications after intraabdominal surgery (19 cases), peritonitis as an effect of digestive tract (five cases) or biliary (two cases) perforation, periappendicular abscesses (two cases), infected pancreatic cyst (three), unknown etiology (three). In all cases septic core body temperature was present, in eight patients increasing multiorgan failure symptoms were present. Abscesses were confirmed by USG in 34 cases (100 per cent), by CT scans in 14 patients (41 per cent).

Results: Repeated laparotomy was carried out 2–10 times in one patient (average four). Fourteen hospital deaths were noted (41 per cent) due to multiorgan failure. In further 10 patients (30 per cent) complications occurred. These were: jejunal and colic fistulas (eight), and mechanical ileus (two). The remainder of the patients left the hospital in good condition. Follow-up period without recurrence ranged from 3 months to 4·5 years.

Conclusions: Repeated laparotomy in cases of large intraabdominal abscesses is an effective method of treatment allowing constant control of the process and proper access in cases of complications.

Thoracic Surgery

Empyema thoracis: a continuous challenge

K. Athanassiadi, G. Kalavrouziotis, A. Loutsidis, I. Bellenis and N. Exarchos *Department of Thoracic and Vascular Surgery, 'Evangelismos' General Hospital, 34A Konstantinoupoleosstr., 15562 Cholargos, Athens, Greece*

Aim: Although empyema thoracis (ET) has been known since the times of Hippocrates, who first described its diagnosis and clinical course, it still persists as a serious thoracic infection, often associated with unacceptably high morbidity and mortality. The present study evaluates the management of 200 consecutive patients with ET treated in our department during the recent 10 year period.

Patients and methods: There were 136 male (68 per cent) and 64 female (32 per cent), aged 21–86 (mean: 51) years. Causes of ET were (post-surgical ETs excluded): pneumonia (63·5 per cent), tuberculosis (11·5 per cent), traumatic hemothorax (6 per cent), ruptured hydatid cyst (5·5 per cent), iatrogenic esophageal rupture (2·5 per cent), various (11 per cent). Diagnosis was based on clinical, radiological and pleural fluid culture findings.

Results: Our patients were divided into groups: group A with acute ET (*n*=97, 48·5 per cent) and group B with chronic ET (*n*=103, 51·5 per cent). Tube thoracostomy drainage (TS) was performed in all patients. Forty-four (45·3 per cent) patients of group A and 23 (22·3 per cent) of group B were successfully treated with TS alone. The rest, 133 patients, were submitted to thoracotomy (TT): lung decortication, Eloesser procedure, modified thoracoplasty, segmentectomy, lobectomy or combination of them. Mortality rates were 4·4 per cent in patients treated with TS and 8·2 per cent in those submitted to TT.

Conclusion: Complete drainage and full lung expansion by TS with suction are essential in the management of ET. If these conditions are not achieved operation should not be delayed.

Surgical treatment of bronchiectasis (early and late results)

V. Colanceski and R. Colanceski *Thoracic Surgery Department, Surgical Clinic, Medical Faculty, University of 'St. Ciril and Methodius', Skopje, Fyrom*

Eighty-six surgically treated patients with bronchectasis (49 female and 37 male) have been investigated and long-term results assessed by subsequent medical evaluation. Fifty-one cases were children and 14 adolescents, while 21 patients were adults.

In 39 patients bronchiectasis were sequels of acute bronchopathy in childhood, 25 with persistent or recurrent bronchopneumonia, eight cases of inhalated foreign bodies, 11 underwent surgical resection, with severe bleeding, two cases with surgical resection of localized bronchiectasis were considered in hypoglobulinanemic patients with persistent localized suppuration and symptoms refractory to medical treatment and one patient having had left lower lobectomy for bronchiectasis and athelectasis due to a double aortic arch.

The mapping of anatomic extension of the lesions was performed by bronchography and CT. Selection for surgery included patients having had cough productive sputum, refractory to medical therapy, recurrent episodes of pneumonitis and recurrent major haemoptysis.

Fifty-seven lobectomies (eight bilobectomy – LLL+ML and 13 – LLL with lingulectomy, 23 segmentectomies (six – basal, four – lingulectomies and two – underwent repeated surgical resection) and six pneumenectomies were performed.

Morbidity was seen in nine cases (four atelectasis, three incomplete re-expansion and two small bronchial leak). Hospital death occurred in one patient. Postoperatively, the evaluated long-term results showed 72 per cent of the patients were asymptomatic, 26 per cent improved and 2 per cent unchanged. It can be concluded that localized recurrent bronchiectasis refractory to medical treatment, before development of complications, the surgical resection is limited to lobectomy or segmentectomy and gives the most satisfactory results. At the stage of surgery, the compensatory emphysema is prevented and the ability of lung expand, will be remained.

Thoracic affection in the course of abdominal hydatid disease

A. Güemes, R. Sousa, F. Burdío, J. Torcal, M.J. Palacios, R. Palacín, I. Gil and R. Lozano *Department of Thoracic and General Surgery, University Hospital, Zaragoza, Av. San Júan Bosco 15, 50010, Zaragoza, Spain*

Introduction: Hydatid cyst, a form of echinococcosis, due to the development of hydatis of a tapeworm in the tissues, particularly of liver and lungs, in an endemic disease in our country. It is an extremely rare cause of hepatic tumours in the Western world but the most common cause of hepatic masses in Spain. Among the complications of hepatic hydatid cyst are infection, fistulas, rupture etc. Communication between the thorax and the abdomen is one of the less common but one of the most difficult to resolve.

Patients and methods: A retrospective review (since 1980) of hydatid abdominal disease with thoracic affection, also called 'hydatid hepatothoracic transits' was carried out based on our experience of 468 patients suffering abdominal hydatid disease treated at our institution. Only 15 patients fulfil the criteria of thoracic affection. We have evaluated the clinical findings, physiopathology of this complication, the surgical approach and complications. A distinction is made between this process and others such as a non communicating double hepatic and pulmonary cysts and pleural complications of hepatic hydatid cysts.

Results: Thoracic pain was the most frequent presenting symptom (71 per cent) together with dyspnoea (50 per cent). Other less frequent symptoms were bilioptisis in two cases (14·2 per cent), and vomiting in three cases (21·4 per cent). There were no clear cases of jaundice but one case presented with subicteria. There were also only two patients (14·2 per cent) with septic syndrome and finally, approximately 50 per cent of the cases presented with pain in the right hypochondria.

CT scan was used in most of the patients confirming thoracic affection in all the cases, but MRI is the current investigation having the same accuracy as CT scan. Thoracotomy was the preferred approach in nine cases and radical surgery, totally completed cystectomy, was accomplished in only five cases. Morbidity was 66 per cent (pleural effusions, wound infection etc.) and one patient died on the second postoperative day from respiratory distress. Average time spent in the hospital was 38 days (range seven to 62).

Comments: Morbidity rate was high, as most of the complications were early in our series, when the less radical techniques were used, radical techniques to treat the liver cyst (almost complete removal of the pericyst layer) and abdominal approach should be used in order to avoid complications. Only surgeons experienced in the treatment of both hepatic and thoracic diseases and also in the treatment of hydatid disease should obtain the best results.

Pulmonary seeding from iliac bone echinococcosis

A. Güemes, R. Sousa, I. Gil, R. Palacín, F. Burdío, J. Torcal and R. Lozano *Department of General and Thoracic Surgery, University Hospital, Zaragoza, Av. San Juan Bosco 15, 50010, Zaragoza, Spain*

Background: Pulmonary seeding is an infrequent complication of abdominal echinococcosis. The liver is the most common location of hydatid cysts, other abdominal organs reached less than 20 per cent of the total. The lung is affected when the scolex is able to pass through the liver filter to the vena cava. Facing a pulmonary hydatidosis we must take into account an accompanying liver affection, which occurs in more than 80 per cent. Pulmonary seeding (growing of multiple cysts in both lungs) used to be caused by a ruptured myocardial or hepatic cyst. Seeding from a unique bone location is a rare condition not reported to date.

Aim: We present a unique case of pulmonary hydatid seeding from a bone located hydatidosis in a patient who was diagnosed two years before of right iliac bone cysts. No other location of hydatid cysts were found.

Clinical report: He was a 58 year old patient with no other pathological conditions. He was diagnosed nine years before with iliac bone hydatidosis and had undergone multiple surgical procedures to treat the disease. He complained of cough and thoracic pain two months before presentation, a chest X-ray showed multiple nodules 1 to 3 cm in both lungs. Pelvic X-ray showed an almost complete destruction of right iliac caused by the previous surgeries, but the hydatid disease was stable at this moment. CT-scan findings were multiple pulmonary masses, we did not find any abdominal or myocardial pathological condition. An open chest biopsy confirmed the suspicion of pulmonary hydatid seeding. Haemaglutination was positive for hydatid antigens (1/20480). Due to the massive lung infection surgery was discarded and Albendazole was started, the patient is asymptomatic at this moment and the number and size of the cysts is stable.

Comments: It is well known that pulmonary hydatid seeding can occur from ruptured cyst of the liver, from other abdominal organs, the heart and even from the soft tissue but it has not been reported the bone location as a primary site of lungs seeding. The bones are affected in less than 0·5 per cent of the total location of hydatid cysts which makes this complication so exceptional. Treatment should not differ from the usually recommended, in this case the massive affection of the lungs prevented any surgical procedure. We used Albendazole as the unique therapy reserving pulmonary transplantation in case of massive growing of the cysts.

Isolated lung perfusion with melphalan for the treatment of metastatic pulmonary carcinoma

J.M.H. Hendriks, P.E.Y. Van Schil, A.A.T. Van Oosterom,
P.J.K. Kuppen, P. Lauwers, E. Van Marck and E. Eyskens
*University Hospital Antwerp, Department of Surgery,
Wilrijkstraat 10, 2650 Edegem, Belgium*

Aim: Currently, overall five-year survival for pulmonary metastases is low while systemic chemotherapy provides little benefit. Isolated left lung perfusion (ILuP) with melphalan for pulmonary metastatic adenocarcinoma in the WAG rat was studied.

Material and methods: On day 0, 35 WAG rats (±250 grams) were injected with 2·0×10E6 CC531S cells intravenously (iv). On day 7, rats underwent sham thoractomy; received 0·5 or 1 mg melphalan (MN) intravenously (iv); or left ILuP with buffered hespan (BH), MN 0·5 mg or 1·0 mg. On day 14, the number of pulmonary metastases were assessed by the method of Wexler. Tumour size was scored between 1+ (small) and 4+ (large). Statistical analysis was performed with ANOVA and Student's *t*-test.

Results: All rats survived ILuP. The number of left lung lesions decreased significantly in the ILuP-treated animals with MN compared to controls (see table). MN iv in a dose of 1 mg showed a bilateral decrease of pulmonary metastases whereas the group receiving 0·5 mg demonstrated no effect.

Group	Number of lesions in right lung	Score	Number of lesions in left lung	Score
1. Sham thoracotomy (*n*=6)	200	4+	200	4+
2. BH ILuP (*n*=5)	174±58	3+	171±65	3+
3. MN 0·5 mg iv (*n*=7)	200	4+	200	4+
4. MN 0·5 mg ILuP (*n*=5)	200	2+	28±16*	1+
5. MN 1·0 mg iv (*n*=6)	48±33	2+	27±16	2+
6. MN 1·0 mg ILuP (*n*=6)	200	3+	16±10*	1+

(200=200 nodules or more) (*:$P<0{\cdot}01$ compared to the non-treated right lung and control animals)

Conclusions: ILuP with MN is well-tolerated at a dose up to 1 mg, and decreased the number of metastatic pulmonary nodules significantly for all doses. Melphalan can be considered an effective agent for ILuP of metastatic carcinoma.

Localized benign fibrous tumours of the pleura: prognostic factors

M. Indinnimeo, C. Cicchini, M.R. Limiti, A. Stazi, C. Ghini,
P. Gozzo and S. tti Brozze *First Department of Surgery,
University of Rome, 'La Sapienza', via del Policlinico 155, 00161
Rome, Italy*

Localized fibrous tumours of the pleura, previously classified as localized mesotheliomas, either benign or malignant, originate from a noncommitted cell in the areolar tissue. The nature is established most often at the time of thoracotomy and subsequent histologic examination. Recurrences of even completely excised malignant lesion and sometimes also of benign lesion do occur as local relapse or blood-borne metasases. Five year survival in recurrent disease is poor. We present 10 cases of localized benign fibrous tumours submitted to surgical resection between 1987–1996. Mean follow-up was 41·5 months (23–60). In each one we detected the CD31 and Ki67 values by immunohistochemistry. CD31 is an endothelial cells antigen; its value indicates the vessel's density. Ki67 antibody is directed against a nuclear antigen only expressed in proliferating cells. Only three cases (30 per cent) stained strongly either for CD31 (>185 vessels/mm^2) and Ki67 (>40 per cent): one of them showed bilateral pulmonary metastases and died at 26 months after surgery, one patient showed bone metastases and died at four months after surgery, the other patient is alive and disease-free at one year after surgery. The other seven patients are alive and disease-free. These data seem to suggest that CD31 and Ki67 values could be considered prognostic factors in the evaluation of the localized 'benign' fibrous tumours of the pleura, but this must be confirmed in larger studies. If these data are confirmed it will be necessary to consider localized benign fibrous tumours with high Ki67 score and CD31 value in an intensive follow-up programme.

Value of thymectomy for myasthenia gravis

S. Kollár, S. Sz. Kiss and Sz. Szentkereszty *University Medical
School of Debrecen, 2nd Department of Surgery, 4004 Debrecen,
PO Box 12, Hungary*

Myasthenia gravis is an autoimmune disorder that affects the postsynaptic acetylcholine receptor of voluntary muscle. The aim of this study is to analyse the value of thymectomy in the treatment of myasthenia gravis in 102 patients operated on between 1981–1995.

The female to male ratio was 3·2 to 1. Their average age was 28·7 years, ranging from 11 to 63 years. After myasthenia gravis had been diagnosed, most patients 64 (62 per cent) underwent thymectomy within a year.

For the preoperative staging the modified Osserman classification was used. Stage I 4 (3·9 per cent), Stage II/a 31 (30·4 per cent), Stage II/b 49 (48·1 per cent), Stage III 18 (17·6 per cent). If there is no improvement with medical treatment within a year, we perform thymectomy even in Stage I. Complete removal of the thymus is the logical goal of surgical treatment, that is the reason why we use median sternotomy as an operative technique. Operative mortality did not occur.

Histological types of the removed thymus gland are thymic hyperplasia in one half of the cases, thymic persistency in one third of the cases, thymoma in 14 cases. The mean follow-up period was 72 months. Postoperative results were evaluated with Jaretzki classification as follows: remission 36 (35·3 per cent), asymptomatic 39 (38·2 per cent), improved 11 (10·8 per cent), unchanged 4 (3·9 per cent), worse 2 (1·9 per cent), died 10 (9·8 per cent). The mean wet weight of the removed thymus glands was 20·3 g. There was no relationship between the weight of the thymus glands and the severity of diseases and postoperative results. Randomized studies demonstrate that the results of thymectomy are better than those of medical treatment, although the role of the thymus in the pathogenesis of the disease is not completely understood.

Sarcomatoid carcinomas of the lung: an uncommon tumour

E. Koletsis, S. Moraitis, P. Staylas and M. Douzinas
Cardiothoracic Surgery Department, Naval and Veterans Hospital of Athens, Greece

Introduction: Sarcomatoid carcinomas (SC) of the lung, although rare in absolute sense (0·2–1 per cent), represent the most common malignancies of the airway that exhibit a composition by spindle or pleomorphic tumour cells. As such, there were many erroneous reports of true sarcomas made before the advent of adjunctive pathologic screening including immunohistological and ultrastructural analysis.
Material and methods: Since 1990, two patients (one man and one woman, 54 and 62 years old respectively), were hospitalized with the diagnosis of a lung mass. Both had a history of heavy cigarette smoking and they were presented with cough, haemoptysis, chest pain and diarrhoea in one case. Chest X-ray showed a single discrete mass, well circumscribed, one in right upper lobe and next in left lower lobe. Both patients had complete preoperative staging with CT-scans, tumour markers, and FNA cytologic studies which revealed non small cells lung cancer.
Results: Both patients were operated on Right Pneunonectomy and Left Lower Lobectomy were performed respectively with mediastinal lymph node dissection which revealed N2 disease in one case. Histology of these specimens revealed sarcomatoid carcinomas of the lung, using special immunohistological (reactivity for keratin, epithelial membrane antigen, collagen type IV) and ultrastructural analysis (presence of junctional complex between tumour cells, cytoplasmic skeins of intermediate filaments). Both patients had adjuvant radiation therapy. One patient (woman, 62) is still alive 25 months postoperatively, although the other patient (man, 54) died seven months after operation.
Conclusions: Despite their anaplastic character, most pulmonary SCs are deemed resectable using the criteria established by the American Joint Committee on Cancer. However, the overall prognosis is grim. Adjunctive irradiation and chemotherapy have been used, but, in general, these measures have had little beneficial effect. Improved recognition of such neoplasms should result in more specific and effective treatments for epithelial and mesenchymal malignancies of the airway.

Surgical treatment of pleural empyema: preferred methods today

T. Laisaar, A. Ilves, S. Suba and T. Vooder *Department of Thoracic Surgery, Tartu University Lung Hospital, Riia str. 167, EE2400 Tartu, Estonia*

Aim: To analyse surgical treatment of pleural empyema and clotted haemothorax in our hospital.
Material and methods: Forty-three patients were treated during two and a half years. Fifteen patients had post-thoracotomy pleural empyema, 23 patients developed empyema due to other reasons and five patients had post-traumatic clotted haemothorax. Post-pneumonectomy pleural empyema was treated with omentoplasty plus partial thoracoplasty in eight cases and with myoplasty plus thoracoplasty in one case. Post-(bi)lobectomy empyema was managed by partial thoracoplasty alone (three patients) or by open-window thoracostomy followed by thoracoplasty (two patients) when gross wound infection was present. In one patient a foreign body causing empyema had to be removed. All patients, except those with open-window thoracostomies were managed by a single operation. Early empyemas with other aetiology and haemothoraces (10 patients) were managed by VATS debridement. VATS was used also in two patients for establishment of proper pleural drainage before definite operations were performed. Organizing stage empyemas (16 patients) underwent decortication and partial parietal pleurectomy.
Results: Three cases of mortality occurred after operating on patients with postthoracotomy pleural empyema (20 per cent), others recovered without major complications. During mean follow-up period of 14·8 months one recurrence of brochopleural fistula occurred and one patient died two months after the operation. VATS debridement was effective in nine patients (90 per cent), one patient needed thoracotomy and lower lobectomy due to lung abscess. All patients managed by decortication recovered without complications. During mean follow-up period of 17·8 months no mortality or recurrence of empyema occurred.
Conclusion: Early pleural empyemas can be effectively treated by VATS and organizational stage empyemas by decortication. Preferred treatment method for postpneumonectomy empyema is omentoplasty.

Role of subcarenal lymphadenectomy in peripheral T1-T2 lung carcinoma of upper right lobe

G. Liguori, M. Cortale, *A. Balani, G. Masullo, *C. Simeth, C. Dapas and M. Maffessanti *Divisione di Chirurgia Toracica, Ospedale di Cattinara, Strada di Fiume, Trieste, Italy.*
**Istituto di Clinica Chirugica, Università degli Studi di Trieste*

According to Tsuchiya (1997) dissection of subcarenal nodes is unnecessary in peripheral non-small cell carcinoma both because of the very low involvement of these stations and the poor prognosis of these patients. In order to verify this statement we analysed our series of 70 upper right lobectomies for peripheral T1-T2 carcinoma histologically thus divided: 27 (38·6 per cent) squamous cell, 26 (37·1 per cent) adenocarcinoma, 13 (18·6 per cent) undifferentiated, three (4·3 per cent) bronchioloalveolar and one (1·4 per cent) carcinosarcoma. We also defined mediastinal nodal metastasis without lobar and/or hilar involvement as 'skip metastasis' classifying them as single and multilevel metastasis. We observed 17 mediastinal metastasis (11 single level skip metastasis and six non skip metastasis). Metastasis of the subcarenal nodes were present in four patients, 5·7 per cent of the cases (one single skip metastasis and three non skip metastasis). In two patients the histological type was undifferentiated carcinoma and in the other two spindle cell carcinoma. Of the four patients one died 11 months after surgery while the other three are still alive at 5, 10, and 12 months. As Tsuchiya (1997) we also observed a low incidence of subcarenal metastasis (4 per cent and 5·7 per cent respectively). However, in our opinion a complete mediastinal dissection is still a necessary procedure in intraoperative staging of peripheral T1 lung cancer.

Surgical treatment of mediastinal lymphangiomas (ML) in children

V. Michailova, R. Drebov, Tz. Boshnakova and I. Jotov
Department of Pediatric Thoracic Surgery, Medical University, Emergency Medical Institute, Pirogov Sofia 1606, Bulgaria

For a period of 18 years (1981–1997) we operated on seven children with ML. The age of the patients ranged from one to six years (five girls and two boys). Five of them were with clinical signs of enlarging tumour mass in the neck, three had dyspnea and one was with deformity and venous congestion in the cervical region. All patients underwent complete clinical examination including conventional X-ray, sonography, angiography, bronchoscopy, bronchography and computertomography. In two children the tumour was found in the mediastinum and in five was located in the mediastinal and cervical region. The X-ray examination revealed tumour mass in the superior mediastinum, in five cases with homogeneous, in one child with inhomogenous and in one case – with hydroaeric level. The sonography and computertomography showed the exact localization, size, structure and the relation of the tumour with the adjacent organs. In two cases the tumour had caused compression and heavy dyspnea. Puncture of cervical lymphangioma and traheostomy were undertaken. All children were operated on – total extirpation of the tumour mass was performed. When the lesions were not well encapsulated the removal was a bit difficult. Two postoperative complications were observed – hylothorax and phlebectasis of superior vena cava. Morphologically the surgical specimens were composed of cavernous lymphatic spaces and the findings were consistent with cystic hygroma. The cystic structures were lined by endothelial cells and separated by a scant intervening connective tissue stroma. There was no well formed capsule.

Conclusion: ML, although histologically benign, tend to increase in size both by collection of fluid and budding of pre-existing spaces. In this manner they compress the vital mediastinal structures, may cause serious clinical problems and need surgical treatment. Total extirpation should be performed to prevent recurrence.

Role of video-assisted thoracic surgery (VATS) in the treatment of primary empyema thoracis (PET)

T.F. Molnar, I. Benkö and Ö.P. Horvath *Department of Thoracic Surgery, First Clinic of Surgery, University Medical School of Pécs, Hungary, H-7643, Pécs*

Aim: A retrospective study was performed to evaluate the value of VATS technique in PET. Primary empyema was defined as intrapleural inflammatory process requiring evacuation without previous surgical or other traumatizing event in the field.

Material and methods: Thirty-one consecutive cases of PET were analysed. The phase of the empyema was categorized according to Moores. In 18/31 cases positive anamnesis with correct timing was found. In 13/31 cases ultrasonography with or without CT confirmed the stage of the PET. Thirty-one VATS were performed using the standard technique.

Results: Successful (no further surgery was needed) VATS procedure was performed in 9/10 cases in phase one PET (anamnesis under four weeks). 8/12 fibrinopurulent cases were solved with VATS alone (history up to 6/52). Only two out of the nine phase three were coped with VATS alone.

Conclusion: VATS seems to be the proper method of choice in PET in phase one and two (history less than 6/52). It is suitable for: 1. evacuation, debridement; 2. phase-staging, checking; 3. reconnaisance: fistula? VATS should be avoided in late phase (organizing) PET (history over six weeks).

DNA ploidy as a prognostic marker in completely resected non-small cell lung cancer

J.M. Mugüerza, J.A.L. Asenjo, M. Díez, A. Gómez, A. Torres, J. Granell, F. Noguerales and J.L. Balibrea *Servicio de Cirugía General, Hospitales Clínico y Príncipe de Asturias, Carretera Alcalá-Meco S/N, 28805 Alcalá de Henares, Madrid, Spain*

Background: DNA content has been proposed as an indicator of outcome in several neoplasms and may reflect its biological behaviour. In the current study, the prognostic information provided by flow cytometric DNA analysis in patients with non-small cell lung cancer was assessed.

Methods: Flow cytometric DNA analysis was performed prospectively in 114 consecutive patients with non-small cell lung cancer submitted to surgery with curative intent. The influence of ploidy on the postoperative outcome was studied by both, a univariate and a multivariate analysis performed with Cox's proportional hazards regression model.

Results: Aneuploidy was found in 67 patients (59 per cent). Overall 36 month survival was 65 per cent for the euploid group and 30 per cent for the aneuploid group (P=0·002). If only stage I is considered, the 36-month survival rate was 72 per cent for patients with diploid tumours and 34 per cent for those with aneuploid tumours (P=0·007). Performing multivariate analysis adjusted for TNM stage and histologic type, bearers of aneuploid tumours exhibited higher risk of relapse (hazard ratio 2·65; CI 95 per cent 1·5–4·66; P=0·004) and death (hazard ratio 2·17; CI 95 per cent 1·08–4·39; P=0·032).

Conclusions: DNA ploidy is an independent prognostic factor of survival and tumour relapse in completely resected non-small cell lung cancer. The authors suggest that DNA ploidy could be a useful parameter in any future multifactorial analysis of outcome in such tumours.

Laser bronchoscopy and stenting: a four year experience

F. Venuta *University of Rome 'La Sapienza', Department of Thoracic Surgery, Policlinico Umberto I, Rome, Italy*

Operative endoscopy of the airway is considered an effective procedure in most departments of thoracic surgery. Between 1993 and 1997 we performed 254 resections within the airway (244 with Nd:YAG Laser) in 200 patients. Thirty-four resections were performed with the flexible bronchoscope under local anesthesia and 220 with the rigid tube under deep sedation; 21 were performed in emergency. Twenty-three patients had postintubation tracheal strictures (33 treatments, 21 stents) and 133 (155 treatments, 41 stents) had malignant lesions (trachea 27, right main bronchus 32, left main bronchus 41, carina four, truncus intermedius 17, left upper lobe six, right upper lobe two, left lower lobe five). Tracheal, laryngeal and bronchial granulations were present in 21, two and four patients respectively. Other lesions were present in 18 patients (anastomotic stenosis after bronchial sleeve resection or lung transplantation in seven and four patients respectively) (31 treatments, 12 stents). Major complications during laser resection were bleeding (five), hypoxia (two), and arrhytmia (two). Two patients died within 24 hours after the procedure performed in emergency. The airway calibre was improved in 100 per cent of patients with benign lesions and 83 per cent of patients with malignancy. In the latter group patency of the trachea, main stem bronchi and truncus intermedius was improved better than lobar bronchi. All patients with malignancy underwent chemo-radiotherapy without respiratory distress; in the group of patients with malignant lesions survival was significantly better when a complete resection was performed. In conclusion, Laser resection is a safe and effective means of releasing airway obstructions. Complications and mortality are minimal. Completion therapy in patients with malignant tumours can be performed without respiratory distress.

Thymectomy for myasthenia gravis: prognostic factors and long term follow-up

F. Venuta, E.A. Rendina, T. De Giacomo, A.M. Ciccone, G. Della Rocca, G. Antonini, E. Guarino, C. Ricci and G.F. Coloni *University of Rome 'La Sapienza', Department of Thoracic Surgery, Policlinico Umberto I, Rome, Italy*

Thymectomy is considered a useful therapeutic option for patients with Myasthenia Gravis (MG). We reviewed our 25-year experience with this procedure with respect to long term outcome and analysis of prognostic factors. Between 1970 and 1996 we performed 218 thymectomies for MG. Fifteen patients were lost to follow-up; the remaining 203 (126 females and 77 males; mean age 36·2 years) form the object of our study. Fifty-six patients (27·6 per cent) had a thymoma. MG was graded according to the Osserman classification: 50 stage I (24·6 per cent), 79 stage IIA (39 per cent), 48 stage IIB (23·6 per cent), 20 stage III (9·9 per cent) and six stage IV (3 per cent). Mean duration of symptoms before the operation was 11·9 months (0·5–42 months). All thymectomies for thymoma were performed through a median sternotomy; 46 thymectomies for non thymomatous myasthenia were performed through a standard cervicotomy and the other 101 procedures were performed through a partial upper sternal – splitting incision; with this approach the resection could be extended to all the perithymic mediastinal fat tissue. Operative mortality was 0·99 per cent (two patients). Mean hospital stay was 6·4 days (7·9 days before 1980 and 4·8 after 1980). After a mean follow-up of 119 months (six to 324 months) 67 per cent of all patients improved their clinical status (21 per cent without medications and asymptomatic; 46 per cent with reduction of medications and clinically improved by at least one stage of the Osserman classification). Favourable prognostic factors were lower stage of myasthenia, absence of thymoma, younger age and short duration of the disease. Thymectomy was effective also in patients with ocular myasthenia gravis. Thymectomy presents minimal morbidity and is effective in the management of patients with mysthenia gravis at all stages of the disease. Patients with thymoma present a less favourable outcome.

Hernia and abdominal wall

Does the patient consider it satisfactory to undergo abdominal wall surgery under local anaesthesia and hospital admission less than 24 hours?

F. Alba, J. Granados, P. Rioja, R. Bonet, J. Briceño, J. Gomez, G. Solorzano, P. Lopez Cillero and C. Pera *Surgery Department of Reina Sofia Hospital, Córdoba, H.U. Reina Sofia, Av Menendez Pidal, s/n 14004 Córdoba, Spain*

Introduction: Early discharge units are becoming more and more established and so is surgery under local anaesthesia, especially for abdominal wall pathology. Therefore it is necessary to assess the results obtained by this type of unit.
Objective: The objective of the following study is to assess the degree of satisfaction of patients that have undergone hernioplasty and herniorhaphies under local anaesthesia and early discharge in our abdominal wall unit.
Methods: We have carried out a retrospective study of a descriptive kind in our series of 210 patients that have undergone hernioplasty and herniorhaphies under local anaesthesia and admission under 24 hours (53 umbilical hernias, 74 inguinal hernias, 48 crural hernias, 22 incisional hernias, and 13 epigastric hernias). Every one of these patients was operated on under local anaesthesia staying in hospital less than 12 hours (one night in hospital). We have polled these patients on the telephone (each of them monitored for 30 months). The questionnaire was drawn up on the basis of the most frequent questions made by the patients in checkups. We have evaluated pain during and after the operation (using a degree scale), the number and period of usage of painkillers after the operation, the most frequent concern on admission and discharge, the choice of this technique in case of private assistance, complications at home, the length of sick leave, incorporation to social life, need of admission or hospital consultation after discharge.
Results: One hundred and seventy-four patients (82·85 per cent) would agree to be operated on again under local anaesthesia, 157 patients (74·76 per cent) felt little or no pain during the operation, 33 patients (15·71 per cent) were in much pain and 20 patients (9·52 per cent) felt some pain. Forty-two per cent of the patients (87) needed painkillers at home for an average of four days. None of the patients had to return to hospital after discharge, although 16·6 per cent (35 patients) consulted their physician in connection with symptoms related to undergone surgery. One hundred and fifty-five patients (73·8 per cent) would recommend this type of surgery to an acquaintance. If they were to undergo surgery in a private hospital, 71·42 per cent (150 patients) would be operated on under local anaesthesia at equal price, this percentage would increase 8·3 per cent (167 patients in all) if the operations under local anaesthesia were more economical. The most frequent complication or discomfort at home was tightness in the surgical wound, 85·71 per cent (180 patients). The utmost concern on discharge was the opening of the skin suture, about 68 per cent (143 patients), and on admission the fact of being discharged within 24 hours, 33·3 per cent (70 patients), and the fear of relapse, 41·42 per cent (87 patients). The average time of incorporation to social life was 9·3 days and to work 25·3 days.
Conclusion: Discharge within 24 hours seems to be safe (no new admission), the method is well tolerated (83 per cent would undergo surgery under local anaesthesia with discharge within 24 hours again). As it can be seen the time on sick leave is long but the incorporation into social life is short.

Massive incisional hernia: surgical technique in the laparoscopic way

M.A. Carbajo, J.C. Martín, J.I. Blanco, C. Cuesta and C. Vaquero
Department of Surgery, Medina del Campo Hospital, 47400 Medina del Campo (Valladolid), Spain

Aim: We report the experience achieved in the treatment of the primary and postsurgical massive hernias the laparoscopic way.
Methods: A group of 30 patients with massive incisive and ventral hernias from different aetiology have been operated on the laparoscopic way in the years 1994–1996. The average postoperative follow-up was two years. The average number of wall defects was two each patients (1–6) and the surface to cover was 140 cm^2 mean (80–275). We used three gateways for access. The defect was treated with a PTFE Dual Mesh with these measures 19 × 15 cm and 10 × 15 cm. Some technical modifications have been produced in the evolution of treatment of the mesh fixing. The external knot and the articulated endostapler have given way to a total internal fixing with helicoidal clamped (Tacker).
Results: The average surgical time was 90 minutes, including three cholecystectomies, the release of adhesions and intestinal incarceration. There were no intraoperative complications or conversion to open. No hernia recurrences occurred. The average of postoperative hospital stay was 2·2 days.
Conclusions: The laparoscopic way avoids large incisions, drainage, seromas and postoperatory infections. It also shortens the hospital stay and shows obvious advantages to classic surgery.

Pseudotumorous reaction of giant cells: report of five cases

J. Comajuncosas, M. Armengol, I. De Torres, M.A. Arbós, J.M. Ferrando, P. Huguet, J. Vidal, S. Schwartz and J. Olsina
Department of Surgery and Pathology, C. d'Investigacions en BiBM, H. Vall d'Hebron, P. Vall d'Hebron 119, 08035 Barcelona, Spain

Aim: To report and compare five cases of pseudotumorous reaction of giant cells and to discard polypropylene mesh as being responsible for this reaction.
Materials and methods: From 1991 to 1996 five patients with a pseudotumorous reaction of giant cells of abdominal wall underwent surgery. Three (60 per cent) were women and two (40 per cent) men, all of them have been operated previously and pseudotumorous reaction appeared in the surgical zone. The previous surgical procedures were: lipectomy in three cases, inguinal herniorraphy (Shouldice's procedure) in one case and repair of a ventral hernia reinforced with polypropylene prosthesis in the other case. All cases underwent large dissections. All patients underwent surgery to resect the lesion and different procedures were employed to repair the abdominal wall. All lesions were histologically evaluated with classic techniques and with electronic microscopy and polarized light.
Results: Histological evaluation of these pseudotumorous reactions showed a fibrotic wall with granulation tissue, dense collagen fibrosis and foreign body granuloma in all cases. Presence of collagen fibrosis and pseudotumorous reaction of giant cells with variegated cells is the reason that this reaction was wrongly called giant cell sarcoma not many years ago.
Conclusions: The histological analysis of all the cases reported did not show any difference between the four cases without mesh and the one with it. In all cases previous surgery was very traumatic with large dissection areas and we thought that this factor summed to an insufficient postoperative drainage of the zone and a possible own phenotypic fibrotic reaction of the patient are the responsibles of the pseudotumorous reaction. We conclude that polypropylene mesh is not responsible for this reaction.

Opinion of the patient vs that of surgeon on the hernia-repair with local anesthesia

B. de Andres, J. Glez-de-Zárate, R.A. de Andres, J. Beltran de Heredia, M.E. Revuelta and J.C. Alvarez
Departamento de Cirugia, Facultad de Medicina, Universidad de Valladolid, c/Ramon y Cajal no.7 Valladolid, 47005, Spain

Aim: To compare the patient's vs surgeon's opinion after inguinal hernia repair under local anesthesia and mild sedation.
Materials and methods: Following institutional ethics committee approval from University Hospital of Valladolid and informed consent from patients, we have studied 278 patients (245 males and 33 females) from March 1997 to December 1997, mean age was 50·5 years (range 15–87) undergoing hernia-repair under local anesthesia with mild seda-

tion. No patient had systemic disease or received medication. The local anesthetic technique used was the infiltration of the operative site with 20 ml Mepivacain 2 per cent dissolved in 60 ml saline solution 0·9 per cent and 1 ml sodium bicarbonate 1 m, and the Major-abdomino-genital and Minor-abdomino-genital nerves blockade with 4 ml Mepivacain 2 per cent. The mild sedation was performed with Midazolam (0·01 mg/kg), alfentanyl (1–5 microgr/kg) and atropine (0·3–0·5). All patients were monitored with pulseoximetry, ECG and blood control pressure. At the end of procedure, we asked the patient to grade the pain with a Visual Analogue Scale (VAS) and to the surgeon, your valoration about the quality-state of patient during surgery (Good: 0–3, Regular: 4–6, Bad: 7–10).
Results:

	Good	Regular	Bad
Surgeon	219 (78·8%)	45 (16·1%)	14 (5·9%)
Patient	252 (90·6%)	21 (7·5%)	5 (1·8%)

$P<0{\cdot}05$ (χ^2-test).

Conclusions: We have found in our study that the patient's evaluation about the procedure is much better than the surgeon one. The reason can be due to the patient's psychological aspects, to the midazolam's amnesic effect or to certain degree of patient's emotional desinhibition during the operation because of the mild sedation. We have very good results on patient's global evaluation about the procedure, that is why we recommend this technique.

Surgical correction of troublesome and persistent postoperative hernias of the abdominal wall

K. Dimitrova, I. Ratchev and J. Rabtchev *Russe, No. 56, Pleven 5800, Bulgaria*

Introduction: Surgical correction of troublesome and persistent postoperative hernias of the abdominal wall continues to be a big problem due to the fact that yearly its frequency continues to increase.
Materials and methods: In the last four years in the first surgical department of the Medical University Pleven, 107 patients with troublesome and persistent postoperative hernias of the abdominal wall were operated on. The patients had had gynecological operations, operations for acute pancreatites, cholecystectomy, umbilical hernias etc. Some of the patients were operated two, three or more (up to seven) times. After undermining the hernial sac, debridement was performed after which inspection of the abdominal organs was done. Plastic surgery of the abdominal wall was then performed: correction with patients tissues – 57 patients, correction with BAPP – 27 and corrections with Mersilene – 23 patients.
Conclusions: 1. The tendency in our series was to perform all corrections with patients tissues. 2. In patients with a lot of musculo-fascial defects, the use of synthetic materials reduces the rate of postoperative complications – Mersiline, or Prolene, is recommended in these cases. 3. Antibiotic prophylactics in patients at risk of infection is mandatory.

Use of the components separation method for closure of abdominal wall defects

M. Geishauser, L. Kovacs and S. Schmiedl *Department of Plastic and Reconstructive Surgery, Klinikum rechts der Isar, University of Technology, Munich, Germany*

Closing large defects of the abdominal wall usually requires an en-bloc-mobilization of the remaining abdominal wall. In cases where this is not possible, pedicled or free flaps are used. Artificial materials like Prolene or Marlex mesh may also be applied. In the acute situation of a burst belly, the wound over the intestine may be allowed to granulate and later be covered by a split thickness graft. Since all these methods are static, they do not allow a full reconstruction of the dynamics of the abdominal wall.

With the components separation method, the rectus muscles as well as the lateral musculature of the abdominal wall become available as local flaps. Since innervation and perfusion will not be altered, the muscular function of the abdominal wall is preserved. A stable closure of the abdominal wall can be obtained, avoiding artificial material like Prolene or Marlex mesh.

In contrast to the static methods mentioned above, the components separation technique is dynamic, which reflects in a good postoperative function of the abdominal wall as well as in a good long-term stability. A prerequisite for the full use of this technique is that the lateral abdominal wall is intact, especially the internal oblique abdominal muscle. In cases where parts of the lateral abdominal wall are not intact, this technique may be used segmentally combined with the use of artificial materials. The components separation method has proven an efficient and reliable technique for the closure of large abdominal wall defects.

A comparison of two 'tension free' inguinal hernia repair methods – laparoscopic hernioplasty vs anterior mesh technique

W. Gontarz, L. Wolański and K. Leksowski *Department of General Surgery, Military Hospital, ul. Powstańców Warszawy 5, 85-915 Bydgoszcz, Poland*

'Tension free' hernioplasty is rapidly gaining worldwide acceptance. This report compares our results with laparoscopic hernia repair (LHR) vs anterior mesh technique according to Lichtenstein (AMT).

From 01.96–03.97 112 patients (comprising 135 hernias) were investigated in a randomized study; we performed 62 LHR and 73 AMT repairs. LHR group underwent transabdominal stapling of preperitoneal Prolene mesh. AMT group underwent open repair with 'tension free' Prolene mesh suturing.

The median long-term results were evaluated based on clinical examination six months (range 3–11) after the procedure. The patients were compared based on Nyhus classification, ASA risk scale and kind of repair. Postoperatively pain was scored in Prys-Roberts scale, it was significantly lower after LHR ($P<0{\cdot}001$). We had to abandon LHR because of serious contraindications to general anesthesia in three cases, the other three cases needed conversion to open repair for technical reasons. In one case we had to remove a mesh a few weeks after AMT due to infection. There were three recurrences: two in LHR group, and one in AMT group.

'Tension free' hernioplasty should be the procedure of choice in the inguinal hernia treatment. The results indicate that LHR is comparable to AMT procedure with respect to postoperative course and complications rate. LHR needs general anesthesia and is more difficult to perform but is better accepted by the patients than AMT repair.

Rives technique under local anaesthesia for difficult inguinal hernia repair: preperitoneal prosthetic placement through the groin

E.J. Grau Talens and F. Olives García *Hospital 'Verge del Toro', Mahón, Menorca, Spain. Calle Ciutadella, 25 07720 Es Castell, Menorca (Balearic Islands), Spain*

Introduction: 25 per cent of the primary hernias and almost all of the recurrent ones require the use of prosthesis. Various techniques have been described for inserting the prosthesis through anterior approach, but only Rives technique repairs all of the herniary orifices of the inguinal region.
Method: We present the total repair of the músculopectineal orifice, through anterior via, using polypropylene mesh, located in preperitoneal space under local anaesthesia. After sectioning superficial planes there follows cremáster section, internal spermatic fascia and the total freeing of the spermatic cord coming out from the properitoneal space. Hernias are identified and the inguinal region is examined. Fascia transversalis is opened up, revealing Cooper ligament and femoral ring. We prepare the polypropylene mesh (6 × 11 cm) which is fixed medially on the posterior of the conjoint area. Follows the suture to the Cooper ligament, femoral fascia, internal inguinal ring, and transversus internal oblique muscles. The mesh stays posterior to the epigastric vessels and posterior wall.
Results: This technique has been carried out on 132 occasions. Mean operation time is 50 minutes; four wound infections; 92 patients followed-up more than two years without recurrences.

Conclusion: Although most of the hernias can be treated with techniques that make use of natural tissues or easier ways to insert the prosthesis, only Rives technique repairs the actual defect and the prophylaxis of the other herniary orifices of the inguinal region through anterior approach

Operative treatment of wide front abdominal wall defects combined with venter propendens

I. Iliev, P. Kazandjiev, P. Krastanov, K. Kyossev, P. Mitev and M. Sirakov *General Surgery Clinic, Military Medical Academy, Sofia, Bulgaria*

Nine patients with wide or with several front abdominal wall defects, combined with venter propendens, were operated in our clinic for a period of three years (1995–1997) These patients being of a 'high risk' group underwent thorough preoperative investigations and preparation. Having in mind the age of the patients, the co-morbidity, the local status and the data of the respiratory and cardio-circulatory tests, the indications for an operation were strictly determined.

The operation passes through the following stages· an 'anchor' shaped incision and wide preparation of the cutaneo-subcutaneous tissues, revision of the underlying aponeurosis, herniotomy and closure of the diasthasis of mm recti abdominis, suturing the subcutaneous tissue and skin closure after applying Redon drainages for 48 hours

This type of combined operative treatment has several advantages On one hand the elimination of the venter propendens, being the main cause for the abdominal wall instability, opportunates an easy and safe abdominal plasty On the other hand the wide operative field facilitates the precise revision of the aponeurosis and its repair In all the patients there was no evidence of recurrent hernias or venter propendens during the follow-up period. Our observations give us the reason to recommend this type of operation as well tolerated by the patients

The open tension-free hernioplasty

M. Lőke *Department of General Surgery, MÁV Hospital, H-5001 Szolnok, Verseghy u. 6-8, Hungary*

10–15 per cent of operations performed in departments of general surgery are for inguinal hernias. One hundred and ten years ago Bassini performed for the first time herniorraphy with acceptable result Since then there have been several modifications of the method The disadvantage of both the Bassini and the modified methods is closing the rings with tensions, which prompts the recurrences. Lichtenstein open tension-free hernioplasty was introduced to our department three years ago The aim of this report is to introduce the method and the early recovery results.

The author performed 71 open tension-free herniorraphies by Lichtenstein method between 1st July 1995 and 31st December 1997 According to this method the rings are closed, anteriorly with Dacron mesh. The method is simple and rapid, less painful than any other technique. Apart from two minor complications, our patients recovered without any problem The method helps to reduce the period of hospital treatment as well as that of sick-leave

Spighelian hernias

M. López Bañeres, J. Rebollo, M. González, A. Minguillón, J. Lagos, J.J. Resa, J M. Del Val, A. Bermejo, A. Cruces and P. López *Obispo Polanco General Hospital, Av Ruiz Jarabo 5, 44002 Teruel, Spain*

Introduction: Spighelian hernias are rare and their diagnosis are difficult due to their intramural placement and the nonspecific symptoms After the introduction of ultrasound and CT scan as routine exams, its diagnosis has been simplified Semilunar line was first described by Adrian van der Spighel, and the first description of a semilunar hernia was done by Klinkosch in 1764 About 900 surgically treated Spighel hernias have been described Mean age of 50·5 years (range 40–70) and are more frequent in women 3-2. Right side is more frequent according to the largest series Although it can be congenital, most are acquired. Main symptoms are nonspecific abdominal pain, mass or intestinal obstruction Differential diagnosis might include lipoma, hematoma and abscess

Aim: To present our Department experience in the treatment of Spighel hernia.

Material and methods: From September 1995 to June 1997, 254 were operated on with the diagnosis of abdominal hernia (inguinal, crural, epigastric, umbilical, ventral and Spighel). Two hundred and eighty one herniorraphies were performed In six patients a Spieghelian hernia was diagnosed and surgically treated as shown in Table

	Age	Sex	Side	Size	Diagnosis	Technique	Evolution*	Drain	Discharge
1	73	Female	Left	15×5 cm	US-CT scan	Mesh	60	–	24 hours
2	55	Female	Right	12×3 cm	US	Suture	96	1	72 hours
3	68	Male	Right	6×3 cm	Clinical exam	Suture	57	–	48 hours
4	59	Male	Right	7×2·5 cm	US	Mesh†	2	–	24 hours
5	63	Female	Right	5×4 cm	Clinical exam	Suture	24	1	48 hours
6	69	Female	Right	8×4 cm	Clinical exam	Mesh	48	–	24 hours

*Months, †Doble Mesh

Results: In our series, 66·6 per cent were female and right side was more frequent (83·3 per cent) than left. In 50 per cent of the cases the diagnosis was made at examination; on the other hand, 50 per cent needed other explorations to reach the diagnosis. The mean size of the aponeutoric defect was 8·8 × 3·6 cm. In two patients (33·3 per cent) there was a slide of right colon and omentum respectively. Time of surgery was 38 minutes (range 30–55). No complications like hematoma, wound infection, seroma or mesh intolerance were observed Stay mean was 40 hours and it was lower in the prosthetic group (24 hours) Analgesic requirements were also lower in the prosthetic group, although no significant differences were observed.

Conclusions: Both suture and prosthetic techniques have good results with no complications and no relpase after a mean follow-up of 13 months (range 6–21) Patient recovery was excellent in all patients.

Tension-free hernioplasty under local anaesthesia for the ambulatory surgery of the inguinal hernia

F. Marsal, E. Caubet, M. Giner, M. González, J. Picas, J.J. Pamies and J.A. Pereira *Department of Surgery, H. St Pau i Sta Tecla 43003, Tarragona, Spain*

Introduction: Tension-free techniques of hernioplasty, based on the systematic use of prosthetic mesh are getting popular among many surgical groups We have analyzed our experience as non-specialized hernia surgeons, with the tension-free technique, local anaesthesia and outpatient surgery

Patients: From October 1989 until September 1996, 1162 patients suffering from groin hernia (n=1425) were operated on by our department in a public hospital Patients mean age was 54 (range 17–90) with a male/female ratio of 5/1. One hundred and thirty eight (9·6 per cent) of hernias repaired were recurrent. After June 1990, 784 operations (55 per cent) were scheduled as outpatient surgery All ambulatory patients had their hernia repaired under local anaesthesia (Mepivacain 0·5 per cent) and sedation with propofol. No contraindication for surgery was made because of age or overweight, and non-operative antibiotics were used

Method: Operative technique. The surgical technique most often used was the tension-free hernioplasty, modified from the description by Lichtenstein et al Briefly, in contrast to these authors we section all cremasteric fibres together with the external spermatic artery and vein and the genital branch of the genitofemoral nerve, at the level of the internal inguinal ring, to get a wide visualization of the posterior inguinal wall. Any indirect sac is opened, inspected and totally or partially excised, except if it has a broad base in which case is inverted A direct hernia is usually inverted. The defect on the transversalis fascia is then sutured with a few 3–0 polypropylene stitches The polypropylene mesh shaped is secured with the same material, caudally to the shelving edge of the inguinal ligament and cranially to the rectus sheath and the internal oblique muscle The slit made vertically to allow the pass of the cord is then closed.

Results: There were no remarkable intraoperative complications. During the immediate postoperative period were recorded 14 per cent complications (hematoma, urinary retention, seroma, abscess). Five patients (0·3 per cent) died with the associated pathology and emergency surgery (no outpatient surgery). Of 700 patients followed up (49 per cent), five recurrences have been detected (0·3 per cent).
Conclusions: Tension-free technique for groin hernia repair result in low complication and recurrence rates, are easily assimilated by most surgeons and performed under local anaesthesia, and facilitate patient's recovery and outpatient surgery.

Convalescence after inguinal herniorrhaphy

A. Duce Martin, F. Arrieta, R. Tobaruela, O. Lozano, R. Villeta, F. Martin, F. Noguerales and J. Granell *Service of General Surgery, Principe de Asturias University Hospital, Ctra Alcala-Meco S/N, 28805 Alcala de Henares, Madrid, Spain*

Inguinal hernia repair is one of the most common operations performed in a general surgical work-load. Though the improvement in suture and prosthetic materials have reduced the incidence of recurrences, today many physicians suggest that a long convalescence period may reduce the rate of recurrence.
Objectives: 1. To know the opinion and the daily procedure of general surgeons and practitioner in relation to the necessary time-off work of these patients. 2. To know the clinical or personal factors that can modify their opinion.
Patients and methods: Between December 1996 and February 1997 a questionnaire was sent to all the general practitioners (GP) (n=2120) of nine Health Areas of Madrid, and to 262 Services of General Surgery of public and private hospitals all over the country. The questions asked were: 1. Following an uneventful primary unilateral inguineal hernia repair in a male between 18 and 65 years, how many days off work do you recommend? 2. Any of the following factors influence you in this time?: a) Type of hernia repair (unilateral/bilateral; direct/indirect). b) Use of a mesh. c) Physical activity of the patient at work (heavy/moderate/light). d) Surgical experience of the surgeon (staff/resident). e) Work conditions of the patient (self-employed or not). f) Wishes of the patient to prolong or reduce this time. 3. Do you usually take the decision to send the patient to work?
Results: A total of 434 general practitioners and 500 surgeons of 89 Services of General Surgery answered the questionnaire. The median time-off work recommended by the GP was 25 (7–68) days. In the surgical group was 27 (6–60) days (p:ns). The physical activity at work (98·5 per cent), the bilateral hernia (74 per cent) and the use of prosthesis (53 per cent) were the factors with the most influence in the group of GPs. Only the physical activity (94 per cent) and the number of hernias (62 per cent) were the factors that influenced the prolongation of the period of convalescence in more than 50 per cent of the surgeons. Only 28 per cent of the surgeons were responsible for the decision to send the patient to work. By contrast, 85 per cent of the GPs took this decision.
Conclusions: 1. GP and surgeons are influenced by factors that have not any consequence in the recurrence rate. 2. Though the theorical time-off work period is similar in both groups (25 vs 27) days, so many factors prolong unnecessarily this time. 3. An update of the implicated physicians is necessary to get a reduction of this excessive period of inactivity.

Method of repair for combined groin hernias

D. Nedin *8 Bialo more Str. 1527 Sofia, Bulgaria, UH 'Queen Giovanna' Clinic of Abdominal Surgery*

The repair of large, recurrent and combined groin hernias with a femoral element during the open herniorraphy is performed mainly by McVay's, Kukujanov's and tension-free techniques. The aim was to work out a method applicable in these cases, providing a possibility for: better repair of the deep inguinal ring, physiological defence of the ring and the posterior wall, preservation of the anatomic structure of the groin area. This was achieved by the method containing the elements of Shouldice's and Kukujanov's techniques.
Material and method: The hernia sac(s) is removed. The iliopubic tract is divided from the inguinal ligament only in its medial half. The pubic pecten and ventral part of Cooper's ligament are approachable. Two (rarely three) stitches pass in the medial half of the latter. The transversalis fascia is cut and it only is repaired using Shouldice's technique. The stitches (inserted through Cooper's ligament) remained extrafascial. The relaxing incision is made through the rectus sheath. The stitches (inserted through Cooper's ligament), are placed also through the lateral part of the rectus sheath and are tied (Kukujanov's element). Without resection of the cremaster muscle, the spermatic cord is replaced on the new inguinal floor. The method cannot be performed in cases with extremely large femoral ring and Hesselbach's triangle. The method was performed in 168 patients, of them: 51 with combined, 18 with large and 17 with recurrent groin hernias. Only one recurrence.
Conclusion: The functional results are very good.

'One stop' day case groin hernia repair

D.W. Oliver, P.K. Eames, V.M.F. Kernick, D.J. Sanders and J.F. Thompson *Departments of Surgery, Anaesthetics and Clinical Audit, Royal Devon & Exeter NHS Trust, Exeter, UK*

Traditionally, an outpatient appointment before hernia surgery is used to confirm the diagnosis, the indications for surgery and to discuss the surgical and anaesthetic options. We present our experience with a direct admission, same day service.

Patients were booked for 'One Stop' surgery if they appeared suitable on the basis of the GP's referral letter, occasionally supplemented by telephone enquiry. A standard explanatory letter was sent to patients and GPs prior to surgery. Follow-up was by postal questionnaire at a median of 16 months. There was a 94 per cent response rate.

Of 81 consecutive patients treated in the day case unit for groin hernia, 50 underwent 'One Stop' repair, 31 were seen in clinic before surgery, usually because of suspected medical co-morbidity, but no other patients accepted the option of a clinic appointment offered in the standard letter.

	'One Stop' (n=50)	Seen in clinic preoperatively (n=31)
Age (years)	54 (18–75)	51 (18–71)
Referral – surgery (weeks)	11	18
Wrong diagnosis	1	2
Local anaesthetic	36%	52%
Return to work (weeks)	2 (1–10)	3 (1–9)
Overall satisfaction	89%	73%

median (range)

One patient was deferred due to mild hypertension (declined LA) and three patients (4 per cent) were admitted overnight. Ninety-eight per cent of the 'One Stop Group' and 97 per cent of the conventional group would opt for the same approach if they developed a contralateral hernia.

'One Stop' day case groin hernia repair is a safe, acceptable technique, with a high level of overall patient satisfaction. In our experience minor queries during the postoperative period are common, so we now telephone patients at one week, with the option of attendance at the day unit, if they are worried.

Results of mesh-plug hernioplasty

M.I. Pirski, P. Witkowski, W. Adamonis and M. Łukiański *I Department of Surgery, Medical University of Gdańsk, Debinki 7, 80-211 Gdańsk*

Aim: Evaluation of the mesh-plug method in the treatment of inguinal hernia in a prospective trial.
Material and methods: In the years 1992–1997, 187 mesh-plug hernioplasty was performed in 182 patients with inguinal and femoral hernia. Hernia type was evaluated according to Gilbert's (Rutkow) classification.

Type 2 and 3 was the most common, 55 and 68 patients respectively. In most patients spinal and local anaesthesia was performed, only 13 (7 per cent) had general anaesthesia. The operation was performed according to Lichtenstein and Rutkow procedure using polypropylene and polyester meshes.
Results: The duration of operation varied from 20–90 (mean 35) minutes. Depending on the anaesthesia applied, patients were mobilized on the same or next day. In most cases (75 per cent) analgesics were administered only during the operation day. Complications were observed in 11 patients (6 per cent), wound infection in four, inguinal hematoma in four, scrotal oedema in three. Hospitalization time was 2–6 days (mean four). Return to normal life activity was two weeks after the operation. Up to date follow-up 1 to 71 months, hernia recurrences were noticed in one (0·6 per cent) patient.
Conclusions: 1. Mesh-plug hernioplasty is simple and effective procedure of inguineal hernia repair. 2. This procedure enables short hospitalization and quick return to normal life activity.

Critical analysis of prosthetic mesh in hernia surgery

S. Sökmen, H. Astarcıoğlu, T. Ünek, E.C. Süzen, A. Önal and M. Füzün *Dokuz Eylül University, School of Medicine, Department of Surgery, 35340 Inciraltı, Izmir, Turkey*

Recurrent hernias remain one of main surgical problems. There is still persistent reluctance in the minds of many surgeons about the usage of mesh products. We aimed to report our experience about the rates of infection, rejection, and of hernial recurrence with the use of prosthetic mesh in the treatment of abdominal wall hernias. Between January 1976 and December 1996, 86 ventral and 15 inguinal recurrent hernias were treated. There were 32 men and 69 women, with an average age of 54 years (range: 17–84). Average follow-up was seven years. Of these, 61 (60·4 per cent) were originated from midline incisions. A polypropylene or a dacron mesh was used to reinforce repairs or to bridge tissue defects. We found a 5 per cent rate of seroma formation and a 2 per cent rate of infection. These complications were managed conservatively. Reherniation occurred in four patients (4 per cent). There were no complications related to adhesions, erosion of the viscera, bowel obstruction and fistula formation. This study suggests that the problem of hernia recurrence can be effectively solved by using prosthetic mesh.

Surgical treatment of hernias in Kėdainiai Central Hospital

E. Stankevičius and V. Kasperavičius *Kėdainiai Central Hospital, Kaunas Medical Academy, Department Physiology, Mickevičiaus 9, LT-3000 Kaunas, Lithuania*

Hernia is one of the most frequent diseases treated in the Surgical Department of Kėdainiai Central Hospital and makes up to 13·7 per cent of all operations performed in the Department.
Aim: We wanted to analyze early follow-up results of hernias surgical treatment in the Surgical Department of Kėdainiai Central Hospital.
Material and methods: Four hundred and eight hernioplastic operations were performed during the period of 1991–1996. The inguinal hernias make up the major part – 73·2 per cent, umbilical hernias – 18 per cent, and femoral hernias – 8·8 per cent. Pediatric operations make 9·6 per cent of all hernia operations. There were 62 (15·2 per cent) of incarcerated hernias. In these cases the resection of small intestine was performed. During 1995–1996 operations on adults were performed: 1) 43 per cent hernioplasty of the posterior wall; 2) 57 per cent hernioplastic modo Kimborovski (Girrard). Lately more often the back abdominal wall is strengthened, e.g. in 1991 only for 11 per cent of patients this method was used. The method of Schumacher is used for pediatric patients. Local anaesthesia was performed for 85 per cent of patients, general anaesthesia for 15 per cent of patients. Only general anaesthesia was used for umbilical and for all recurrent postoperative hernias, and it makes 5·3 per cent of all the hernias. General anaesthesia is performed for all pediatric patients. There were observed these complications: 1) the local infection of the incision – 2 per cent; 2) pneumonia – 1 per cent; 3) 3 (0·7 per cent) patients who had incancerated hernias died.
Conclusions: 1) Lately the method of strengthening of the back abdomonal wall is used more frequently. 2) The recurrent hernias are rare.

Mesh-plug inguinal hernia repair vs Bassini procedure randomized trial

P. Witkowski, M.I. Pirski, J. Kostro and M. Łukiański
I Department of Surgery, Medical University of Gdańsk, Debinki 7, 80-211 Gdańsk

Aim: Evaluation of the mesh-plug method in the treatment of inguinal hernia.
Material and methods: One hundred and forty patients treated for inguinal hernia were submitted to randomized and prospective trial. Hernia type was evaluated according to Gilbert's (Rutkow) classification. Two types of procedures were performed: group I – (58 patients) – the Bassini operation and group II – (82 patients) – 'mesh-plug' according to Lichtenstein and Rutkow. Statistical analysis was based on t-Student and Mann–Whitney tests. There were no significant differences between the groups in the patient's age, hernia types and the types of anaesthesia.
Results: Duration of operation in group I: 30–150 minutes (mean 66·4±26), in group II: 20–90 minutes (46±15). Statistical analysis revealed significant difference between these two groups. In 34 (58 per cent) patients of group I and in 17 (22 per cent) of group II narcotic analgetics were necessary. The difference was significant at P level $<0{\cdot}05$. Postoperative complications were observed in six (10 per cent) patients from group I and in nine (11 per cent) from group II. Duration of hospitalization in group I was 3–15 days (mean 5±2), in group II 1–11 days (mean 4±2). Patients from groups I and II returned to their normal activity after four weeks and two weeks respectively. In the follow-up 1–27 months no hernia recurrences were observed.
Conclusions: Shorter operating time, less painful postoperative course and faster recovery are the advantages of mesh-plug procedure.

Prophylaxis with ampicillin-sulbactam prevents wound infections after prosthetic inguinal hernia repair

M.A. Yerdel, E.B. Akin, A.G. Türkçapar, M. Pehlivan, B. Erkek and E. Kuterdem *Ankara University Medical School, Ibni Sina Hospital, Department of General Surgery, Ankara, Turkey*

The value of prophylactic, single dose intravenous ampicillin-sulbactam (AS) in the prevention of wound infections in patients undergoing prosthetic inguinal hernia repair was assessed. This study appears to be the first prospective double blind controlled trial addressing this tissue.

Between September 1996–December 1997, patients (n=150) undergoing primary unilateral inguineal hernia repair without systemic disease were entered our protocol. Patients were administered AS (n=75) or placebo (n=75) intravenously prior to incision according to a predetermined code which the surgeons are unaware. Lichtenstein repair under local anesthesia was the technique adopted. Age, sex, body mass index, duration of operation was recorded. Patients were evaluated one week and one month postoperatively by the same surgeon. Any discharge was sampled and cultured. Wound infection was defined as discharge from the wound with positive culture. Upon completion of the study period the code was broken and results were assessed utilizing Student's t and χ^2 tests.

Groups were well matched for age, sex, body mass index, duration of operation and postoperative complications excluding the rate of wound infections which occurred at a rate of 0 per cent in AS opposed to 8 per cent in placebo group ($P<0{\cdot}05$). Six patients in placebo group developed wound infections (8 per cent) requiring rehospitalization in five and in two patients grafts were removed due to persistent infection.

This study documented decreased rate of wound infections when single dose AS was used during Lichtenstein inguinal hernia repairs. Proponents of mesh repairs are advised to use prophylactic single dose intravenous antibiotic coverage during their repairs. AS seemed to be an effective agent in the present study.

Free radicals in the pathomechanism of haemarthrosis

B. Borsiczky, M.T. Jaberansari, E. Rõth and *Gy. Zadravecz
*Department of Experimental Surgery and *Department of Traumatology, University Medical School of Pécs, Kodály Z. u. 20, 7624 Pécs, Hungary; Ifjúság u. 13, 7624 Pécs, Hungary*

Haemarthrosis (HA) as a cause of cartilage degradation is still a problem in traumatology. Early development of arthropathies in patients active in sports is already known. We think that repeated haemarthrosis may cause such complications. Till now most studies have investigated the morphological changes following haemarthrosis and estimated the effect of haemarthrosis but only in vitro conditions. In this in vivo trial we tried to explain the blood induced morphological changes in cartilage as well as clarifying the pathomechanism of haemarthrosis via a hypothetical model. We aimed to elaborate on the role of polymorphonuclear leukocytes and oxygen radicals following acute haemarthrosis hence trying to prove an important part of our model. Twenty four mongrel dogs were used. Artificial haemarthrosis was produced in their left hind knees by intra-articular injection of their own blood. The right hind knees served as control. The dogs were divided into three groups based on the time of haemarthrosis (1–7–30 days). Samples of the condylar cartilage were submitted for biochemical examinations to measure products of lipid peroxidation (malondialdehyde) (MDA), the reduced glutathione (GSH) and the activity of superoxide dismutase (SOD) by spectrophotometry. The changes in values were expressed in percentages where the control served as zero per cent. The 30 days samples were also examined by scanning electron microscope (SEM). There were no significant differences of biochemical parameters of one day samples. By the seventh day GSH and the activity of SOD increased by 45·3±3 per cent and 27·2±5·8 per cent respectively in the HA samples, while the MDA remained practically unchanged. In the one month samples there was no further increase in the production of endogenous scavengers but the GSH level was dropped to 17·3±8·2 per cent. The activity of SOD also decreased by 5·0±4·8 per cent as compared to the control. However, the intensity of the lipidperoxidation increased by 18·8±14·9 per cent. Morphological analysis by SEM revealed some damage of the cartilage after one month. Instead of a normal surface the cartilage showed abrasion-like injuries. These results suggest that induction of protective mechanisms such as increased production of free radical scavengers may hinder lipidperoxidation in the early phase of HA. On the contrary the balance between the defensive and aggressive processes tend to shift towards the more aggressive after one month. Therefore the first detectable morphological changes following HA seem to appear after one month or even later which correlates with the biochemical variations. Our model allowed us to prove our assumption that the free radical associated reactions play an important role in the pathomechanism of HA. All of these findings have encouraged us to further continue this investigation.

Use of low molecular weight heparin (Enoxaparin) in preventing venous thromboembolism in multiple trauma patients

K. Dolay, M. Kurtoğlu, R. Güloğlu and A. Necefli *Department of Emergency Surgery, Medical School of Istanbul University, 34390 Çapa, Istanbul, Turkey*

Aim: To investigate the safety and effectiveness of low molecular weight heparin (LMWH) in preventing thromboembolism in immobilized multiple trauma patients.
Material and methods: Between February 1996 and May 1997, 40 mg Enoxaparin (Clexan; Eczacıbası, Rhoune-Poulenc) was given subcutaneously once daily to the immobilized multiple trauma patients who were managed at the Intensive Care Unit of Emergency Surgery Department after their diagnoses were established. Seventy-six patients who stayed at the hospital at least seven days were included in this study and Enoxaparin administration (40 mg per day) was continued until the patients were mobilized. All trauma patients with one or more following risk factors for the development of VTE (age >45 years and enforced bed rest >3 days; previous history of venous thromboembolism; Glasgow Coma Scale <7; quadriplegia/paraplegia; spine, lower extremity or pelvic fractures; injury of a major lower extremity vein; complex wound of lower extremity) were assigned to the high-risk group. If none of the factors was present, the patient was assigned to the low-risk group. Twenty-six patients in high-risk group underwent bilateral contrast venography with nonionic contrast (Omniopaque 300 mg) to screen DVT at seventh day routinely after injury. Six patients suspected of having PE on clinical findings (tachycardia, tachypnea, chest pain) in high-risk group underwent ventilation perfusion scanning. Three of 50 patients suspected of having DVT based on clinical findings (pain, swelling, calf tenderness) in low-risk group underwent venography. There were no findings suspicious of PE in this group.
Results: None of the patients developed DVT, a ventilation perfusion scanning was assessed being as a suspected PE. Bleeding complications due to the use of Enoxaparin were not observed.
Conclusion: The use of Enoxaparin in preventing VTE in multiple trauma patients is safe, effective and necessary.

Laparoscopy in blunt abdominal trauma

A. Grigaliūnas, E. Gaidamonis, J. Stasinas and S. Tamulis
Vilnius University Emergency Hospital, Siltnamiu 29, 2043 Vilnius, Lithuania

Aim: To assess the safety and efficacy of diagnostic laparoscopy in the diagnosis of intra-abdominal injuries in hemodynamically stable trauma patients, in absence of peritonitis, presence of severe concomitant injuries, objective difficulties in obtaining diagnosis, as well as to directly compare laparoscopic findings with the results of subsequent laparotomy in each patient.
Material and methods: Between January 1993 and December 1997, 51 patients with blunt abdominal trauma who were hemodynamically stable underwent diagnostic laparoscopy. All laparoscopic examinations were performed in the operating room under general anesthesia in 40 patients and local anesthesia in 11 patients. The laparoscope was introduced via a canula in the infraumbilical position. A 10–14 mmHg pneumoperitoneum is created using Verres needle, 10-mm umbilical trocar and one or two 5-mm trocars are inserted for manipulation. The mean time for performing laparoscopy was 27·1 minutes. No complications related to laparoscopy occurred.
Results: There were 36 males and 15 females ranging in age from 17 to 83 years old (mean = 35·2 years). Evidence of intraperitoneal injury was identified at laparoscopy in 41 patients. In 33 of these, laparotomy was felt to be necessary based upon the laparoscopic findings. Subsequent exploration revealed injuries requiring open treatment in all 33 patients. In eight patients injuries (six patients with hepatic bleeding I-II grade injuries) were treated, using laparoscopic technique. Ten of the laparoscopies were with no evidence for intraperitoneal injury. But in one patient a small bowel injury was missed.
Conclusions: In our patients diagnostic accuracy was 98·1 per cent, sensitivity – 88·9 per cent and specificity – 85·6 per cent. Diagnostic laparoscopy resulted in 0 per cent nontherapeutic laparotomy rate. Thus, diagnostic laparoscopy could be safely performed in the hemodynamically stable blunt abdominal trauma patients, who have indication for laparotomy based on standard diagnostic criteria. Laparoscopic findings in the most cases predicted the need of subsequent laparotomy.

Monitoring of oxidative stress parameters after resuscitation following haemorrhagic shock

M.T. Jaberansari, B. Borsiczky and E. Rõth *Department of Experimental Surgery, University Medical School of Pécs, Kodály Z. u 20, 7624 Pécs, Hungary*

The haemorrhagic shock (HS) is a major factor contributing to fatality in polytrauma patients. Nowadays in clinics urgent intravascular volume restoration and tissue perfusion is widely accepted as an important part of management. However, reperfusion injury is a special side effect of this beneficial intervention due to escalation of oxidative stress. Because the kidney is amongst the first organs to be affected by HS, in our in vivo study we aimed to elaborate on the effects of resuscitation on kidney following such an insult. In contrast to clinical practice we were able to compare blood samples taken peripherally to that taken from the renal vein itself, paying particular attention to markers of reperfusion injury. HS was induced in 11 mongrel dogs by way of artificial bleeding, lowering the mean arterial pressure (MAP) to 45±5 Hgmm. This pressure was maintained for two hours. Then blood was reinfused over 30 to 45 minutes and the dogs were observed for a further two hours. Haemodynamic parameters, ECG and capillary flow by laser Doppler were registered continuously. Blood samples were taken at certain time points throughout different phases of the experiment. Product of lipid peroxidation (malondialdehyde) (MDA), reduced glutathione (GSH) and the activity of superoxide dismutase (SOD) were measured by spectrophotometric method. The stimulated superoxide radical generating capacity and the lag time of polymorphonuclear leukocyte (PMN) activation were also measured. Tissue samples from the kidney were taken for measurement of the same parameters. It was observed that although MAP normalized (85·1±5·5 Hgmm) by the end of reperfusion, the rate of microcirculation in kidney remained subdued by 32 per cent throughout reperfusion. We found changes in MDA to be statistically insignificant, yet scavenging activity of GSH was noticeably lower (from 21·9±0·9 to 12·7±0·7 nmol/ml) in blood taken directly from renal vein when compared to peripheral blood. Free radical production capacity of PMN's showed a gradual decline in both types of blood samples; however, discrepancies were observed in the lag time. Namely there was a gradual rise in the peripheral blood whilst in renal vein samples after an initial fall to 1·0±0·3 seconds from 1·3±0·1, a sharp increase was noticed following reperfusion (2·2±0·2 seconds). In conclusion it is evident that following resuscitation from haemorrhagic shock there is a triggering of oxidative stress processes with resultant decrease in scavenging activities and PMN activation. Secondly, it has been shown that to monitor changes in these parameters they are better demonstrated by a more selective approach to blood sampling.

Duodenal injuries

A. Kitanovic, R. Djordjevic, M. Miladinovic, M. Smiljkovic, D. Stankovic, V. Kulic and M. Cajic *Health Centre Krusevac, Department of Surgery, Krusevac, Yugoslavia*

This work presents our experiences in surgical treatment of duodenal injuries caused by blunt and penetrating abdominal trauma.

Within the period 1988–1997, 12 patients were surgically treated having abdominal trauma and duodenal injuries. Clinical picture analysis elaborated the mechanisms of injuries, diagnostic procedures, the ways of surgical care as well as postoperative complications. In the same period we had 617 patients with abdominal organ injuries.

In 10 patients the injury was caused by blunt and in two patients by penetrating abdominal trauma. In only one patient the injury of duodenum was separate and in all others was associated with the pancreas, mesocolon transversum, stomach, spleen and liver injuries. Injury diagnostic was established during the operation when bile-stained duodenal contents was found and mobilization of duodenum by Kocher manoeuvre was effected. In three patients duodenal lesions were solved by only suture of perforation. Another three duodenal lesions were solved by suture with pyloric exclusion and side to side gastrojejunostomy, and in six cases injuries were solved by covering of lesion with Roux-en-**Y** duodenojejunostomy. After the operations decompression with nasogastric tube was usually continued until bowel function returned. Five lesions were localized at the second portion, and seven of them at the third and fourth duodenum portion.

As for postoperative complications we have had four wound infections. Average hospitalization used to be 17 days.

Duodenum injuries are rare, but inspection of the whole duodenum is important during the abdominal exploration. We have had the best results with Roux-en-**Y** duodenojejunostomy.

MRI vs endoscopy in the diagnostics of knee surgery

J. Németh, *A. Vargha and S. Nábrádi *Dr. János Németh, H-9400 Sopron, Győri út 15, Traumatológia, Sopron MJV Erzsébet Kórház*

The number of patients requiring examination and treatment due to injury of knee joint and to degenerative alterations has been increased significantly in the past years.

The authors analyse whether in their own practice the examination through non-invasive MRI or endoscopy (arthroscopy) proved to be the most expedient as well as the most economical.

From January 1, 1996 up to December 31, 1997 there were carried out on the whole 344 arthroscopy of the knee joint. Out of this patient group 142 patients required also MR examination before operation.

They compare the two examination methods – each clinical pattern treated separately – analysing their advantages as well as disadvantages, dealing beside their diagnostical accuracy with the economical aspects.

Drawing a conclusion they state that the non-invasive MR examination is very useful in the filtering out of negative cases.

The diagnostical accuracy of the examination by arthroscopy surpasses that of MR, at the same time it gives plus information of manual examination and for the time being it is less costly than that. Moreover, it provides good assistance – if necessary – in the planning immediately before the operation and the examination can be followed without delay by the operation.

Therapeutic priorities in polytraumatized patients with cranial and abdominal lesions

V. Paunescu, A. Kontogiannis and C. Popescu *9A, Ionel Perlea Str., et. I, ap. 3, 70754, Bucharest, Romania*

The study analyses the patients who have injuries of both the head and the abdomen.

Among 5725 patients hospitalized during 1994–1995 in the Emergency Clinic Hospital 'Prof. Dr. D. Bagdasar', 1456 were polytraumatized and 1444 hospitalized in the Intensive Care Unit. Among the 1456 politraumatisms, 206 had associated craniocerebral and abdominal lesions. The most common mechanism of injury was traffic collision (*n*=156; 75·62 per cent), falls (*n*=34; 16·3 per cent), aggressions (*n*=11, 5·33 per cent) and other causes. Males (*n*=148) were most affected. The variation of age (1–84) overlapped the age pyramid.

The computed CT scanner of the head was done in all multiple trauma cases. The diagostic peritoneal lavage (DPL) (*n*=206), CT scanning of the abdomen (*n*=62) and echography were used for the diagnostic of intra-abdominal organ injuries. Among these investigations, CT scanning of the abdomen has the biggest specificity (94·7 per cent) and accuracy (94·6 per cent). Glasgow Coma Scale (GCS), Injury Severity Score (ISS), Revised Trauma Score (RTS) and Abbreviate Injury Scale (AIS) were used to assess the trauma.

In grossly hemodynamically unstable patients, hemoperitoneum was caused by spleen rupture (*n*=17). In hemodynamically stable patients, the incidence of intra-abdominal injuries was: liver (*n*=2), pancreas (*n*=4), kidneys (*n*=6), retroperitoneal hematoma (*n*=18). Peritonitus signs (*n*=18) resulted in laparotomy that identified injuries of the intraperitoneal organs: perforation of the small bowel (*n*=6), mesentery rupture (*n*=5), perforation of colon (*n*=3), stomach (*n*=1) or other stomach injuries (*n*=2). Blunt abdominal trauma without intra-abdominal organ injuries was present at 39 patients.

The mortality multifactorial analysis shows a strong correlation between mortality and shock (66 per cent), between mortality and abdominal lesions (*n*=54 per cent), and between abdominal lesions and shock (*n*=77 per cent).

The diagnosis of multiple traumas is difficult. Those patients had an altered mental status.

The analysis of prehospital and emergency service approach to isolated moderate and severe head injuries in Turkey

R. Tokyay, E. Armağan, H. Özgüc and Ö. Yünük *Emergency Service and Trauma Unit, Uludağ University Medical School, 16059 Bursa, Turkey*

Aim: This study was designed to find out the current status of the prehospital and emergency service approach to isolated severe head injuries (ISHI) admitted to a university hospital in a major city in Turkey.

Material and methods: The emergency service records of 87 isolated head injuries (Glasgow Coma Score, GCS<13) out of 1652 trauma patients admitted to our university hospital between November 1, 1996 and October 31, 1997 were analysed.

Results: Mean GCS was nine and the mean prehospital time was 52 minutes. Thirty-six (41·4 per cent) of the 87 ISHI patients were transferred from another hospital. Twenty-one (41·2 per cent) of the 51 primary arrivals came directly via the ambulance service. All 21 of these patients had their blood pressures measured and 17 of them had IV fluids started at the scene or in the ambulance. Two of these patients had endotracheal intubation and four had cervical collar on arrival. All 87 ISHI patients had their cranial CTs done in the Emergency Service Radiology Unit within one hour. Forty-five patients (52 per cent) were disposed to the intensive care unit, 28 (32 per cent) to the operating room, 14 (16 per cent) to another hospital and two (2 per cent) died in the Emergency Service.

Conclusion: The prehospital phase of our regional neurological trauma care seems to be defective and to improve this care ambulance services must be increased and the ambulance doctors must be trained, especially for cervical immobilization and endotracheal intubation.

Abdominal traumatisms: our experience

A. Vázquez, M.J. García-Coret, E. Montalvá and E. Artigues
Service of General and Digestive Surgery, Valencia University General Hospital, Valencia, Spain

Aim: The evaluation of abdominal traumatisms is essential for the adoption of adequate management measures. In recent years there has been a change in the treatment protocol of such cases, due to the introduction of new diagnostic techniques that allow improved evaluation and management. The protocolization of traumatized patients presently allows a more conservative approach to treatment. We report our experience in the management of abdominal injuries over a three-year period.

Material and methods: A total of 178 traumatized patients were studied. There were 127 males (71 per cent) and 51 females (29 per cent), with a mean age of 33 years (range 5–90). A total of 46 patients (25·84 per cent) suffered abdominal lesions. The causes were evaluated, along with the diagnostic methodology employed, the type of lesion involved, management protocol and outcome.

Results: Of the 46 patients with abdominal injuries, 34 (73·91 per cent) were males. Mean age was 30 years (range 7–77). Traffic accidents were the most common cause (63·1 per cent). There were 30 closed abdominal injuries (65·21 per cent), while 31 patients presented associated extra-abdominal lesions. The affected organs were the spleen (n=38), liver (n=28) and intestine (n=9). There were multiple abdominal lesions in 11 cases. Following initial patient evaluation according to protocol, the diagnostic methods employed comprised echography, CAT and punction-lavage – the latter being performed in six cases (13·04 per cent). Conservative management was adopted in 33 per cent of the liver lesions, and in 26·4 per cent of the splenic injuries. The remaining patients were all subjected to surgery. Global mortality comprised five patients (with multiple intra- and extra-abdominal lesions).

Conclusions: The protocolization of polytraumatized patients is essential in order to standardize diagnostic and therapeutic measures – particularly in cases of closed abdominal injuries. In this way the lesions may be more precisely evaluated and adequate treatment initiated on an individual basis.

The effect of somatostatin on extrahepatic biliary obstruction in rat liver

M.L. Akin, S. Aydin, C. Erenoglu, E. Filiz, S. Yildirim and A. Batkin *GATA Haydarpasa Egitim Hastanesi, Genel Cerrahi Servisi, Kadikoy, 81327 Istanbul, Turkey*

Aim: Extrahepatic biliary obstruction causes biliary duct epithelial cell proliferation and periportal fibrosis. If the necessary intervention is not performed at the right time, the disease may progress to biliary cirrhosis. In this experimental study, the effects of somatostatin analogue octreotide on biliary duct epithelial cell proliferation and periportal fibrosis in rats with extrahepatic biliary obstruction were investigated.

Materials and methods: Thirty female Wistar-albino rats were used. Rats were separated into three groups of 10 rats. In the first group (sham operated group) only laparotomy with common bile duct handling was applied. In the second and third groups (control group and octreotide group) laparotomy and proximal common bile duct ligation are followed by 0·5 ml of saline or 6 µg/kg octreotide subcutaneously twice daily for five days were applied respectively. On the fifth day all rats had relaparotomy and blood samples were taken for serum bilirubin, alkaline phosphatase, SGOT, SGPT measurements, and hepatectomy was performed for histopathological evaluation.

Results: Histopathologically, proliferation and fibrosis scores were significantly higher in control and octreotide groups than those of sham operated group (P<0·05), and they were significantly lower in octreotide group than those of control group (P<0·05). Although the biochemical results were significantly higher in control and octreotide groups than those of sham operated group (P<0·05), there was no significant difference between control and octreotide groups (P<0·05).

Conclusions: It is concluded that extrahepatic biliary obstruction causes severe biliary duct epithelial cell proliferation and periportal fibrosis, and although octreotide prevented these complications histopathologically, there was no improvement observed in terms of biochemical parameters.

Role of Bcl-2 in zinc inhibited apoptosis of rat liver

A. Amin, B. Fuller and M. Winslet *University Department of Surgery, Royal Free Hospital School of Medicine, London NW3 2QG, UK*

Apoptosis is an active DNA fragmentation and cell deletion. It is usually regulated by certain genes expression. Bcl-2 is a well documented gene which saves the cells from committing suicide and apoptotic death. Expression of this gene expands the cellular population by suppressing apoptosis. On the contrary, expression of p53 induces apoptosis and reduce cellular population mass. We have studied the role of Bcl-2 and p53 in isolated perfused rat liver (IPRL) apoptosis model by immunohistochemical staining of rat liver.

Rat livers were perfused with modified Kreb's solution containing glucose and hydroxyethyl starch (Colloid) at 37°C and oxygenated with 95 per cent O_2 and 5 per cent CO_2. Liver specimens were collected at 0, 1, 2, 3, 5 h and freeze clamped in liquid N_2. DNA was isolated using standard phenol chloroform extraction and electrophoresed on 1·5 per cent w/v agarose gel, stained with ethidium bromide 40 µg/L (w/v) and visualized by UV light.

Although there was no evidence of positive expression of this gene in the liver samples with DNA damage after 3 h warm reperfusion at 37°C. Specimens treated with zinc sulphate 25 µM + zinc ionophore 4 µM rich solution (n=8) and proved to have no DNA fragmentation on agarose gel electrophoresis have strong positive staining of Bcl-2 antigen in its cytoplasm and was also consistently associated with negative expression of p53 gene. Furthermore, rat livers treated with antioxidants N-acetyl cysteine or calcium channel blocking agents verapamil were without evidence of Bcl-2 expression.

In summary, rat liver DNA apoptotic degradation may be inhibited by zinc sulphate after induction of Bcl-2 expression. Endonucleases inhibition by zinc may play a part in the gene expression and DNA fragmentation blockage mechanism. Further study is required for more understanding of the role of Bcl-2 in rat liver apoptotic cell injury.

The effects of laparoscopic vs open bilateral truncal vagotomy on the immune system in rats

L. Avtan, E. Berber, C. Avci, İ. Berber, G. Yillar and G. Deniz *University Hospital, İstanbul Faculty of Medicine, Genel Cerrahi 34390, Çapa, Turkey*

Pneumoperitoneum was shown to be less immunosuppressive than laparotomy wounds in the rat, however, to our knowledge, no extensive experimental study has been done to compare the immune system effects of laparoscopy with laparotomy by adding a surgical procedure. We report the preliminary results of an experimental study investigating the changes in immune system in rats undergoing laparoscopic vs open (OBTV) bilateral vagotomy. Thirty-six Wistar-albino rats were divided into three groups including, the control (n:6), LBTV (n:15) and OBTV (n:15) group. Controls underwent laparotomy with a 5 cm midline incision and were sacrificed after blood was drawn from inferior vena cava for baseline values. LBTV was effected with three mini-trocars at 6–7 mm Hg of pneumoperitoneum. OBTV was performed with a 5 cm midline incision. Both of the procedures lasted 30–35 minutes. In each group, laparotomy was performed either 24 hours (n:5), or 72 hours (n:5) after the first operation and blood for analysis was obtained by puncturing inferior vena cava. CD3, CD4, CD8, B lymphocyte, macrophage and granulocyte counts were determined from blood samples by flow-cytometric analysis. As a result, CD3, CD4, B lymphocyte, macrophage and granulocyte levels were not found to be different from the controls in both the LBTV and OBTV groups at either 24 or 72 hours (P>0·05, Kruskal-Wallis). On the other hand, CD8 levels for the LBTV group at 24 and 72 hours were higher than for controls (26·3±10·2 per cent and 36·4±13·6 per cent vs 18±3·2 per cent; P<0·05, Mann-Whitney U). CD8 levels for the OBTV group at 24 hours were also higher compared to controls (32·4±3·2 per cent vs 18±3·2 per cent; P<0·05, Mann-Whitney U) but returned to baseline at 72 hours (25·8±14·9 per cent vs 18±3·2 per cent; P>0·05, Mann–Whitney U). These results suggest that laparoscopic or open bilateral truncal vagotomy does not affect the immune system quantitatively except for the increase in CD8 levels at 24 hours with both procedures which return to baseline at 72 hours with the open procedure. Pneumoperitoneum in the laparoscopic procedure may be responsible for this finding.

Analysis of neutrophils' role on incisional wound healing

N.Z. Cantürk, B. Vural, N. Esen, Z. Cantürk, S. Solakoğlu, G. Kirkali, C. Sökmensüer and N.Z. Utkan *Kocaeli University School of Medicine, Turkey*

Aim: GM-CSF has been used clinically when given systematically to increase circulating neutrophils, but wound healing effects have not been systematically studied. GM-CSF may be physiologic components of a growth factor cascade within healing wounds. The aim of this study is to determine the role of neutrophils and macrophages in the pathophysiological cascade leading to incisional wound healing. In present study, cyclophosphamide and granulocyte-macrophage colony-stimulating factor (GM-CSF) were preferred because of their contrary effects on leukocytes and a number of activities.

Materials and methods: Twenty-four Wistar albino rats were used in this study. Animals were randomized into three groups, controls receiving saline, group II receiving cyclophosphamide and group III receiving granulocyte-macrophage colony-stimulating factor (1000 ng twice per day). In anesthetized rats in all the groups, blood neutrophil counts and neutrophil functions were also determined. Seventh day of wounding, rats were killed. Fresh breaking strengths of wounded skin and hydroxyproline level of wound was determined and wound healing processes was blindly evaluated by light and electron microscopy.

Results: Neutrophil counts and phagocytosis significantly increased in group III and neutrophil counts also decreased in group II (P<0·05). Wound score in the group II was significantly less than that in the groups I and III (P<0·05). Significant differences in breaking strengths were seen between group II and group III (P<0·05). Hydroxyproline levels in surgically removed wounded skin were not also significantly changed for all three groups ($P>0{\cdot}05$).

Conclusion: The present study shows that neutropenia decreases the degree of wound healing. It is concluded that PMNs may have a role in modulating wound healing. Systematically given GM-CSF can enhance the breaking strength of surgical incision during the first week after wounding.

Clinical products and secondary cicatrization in the experimental animal

R. Chacón, J.F. Jiménez, Mª.L. Estévez and B. Rodríguez
School of Nursing, University of Las Palmas de Gran Canaria, P.O. Box 550, Canary Islands, Spain

Objective: This is an attempt to determine the cicatricial effect of bidistilled water and physiological serum on secondary cicatrization and to compare the calculation of the surface area of cutaneous wounds using a direct and also indirect method.

Materials and methods: We performed a 1×1 cm cutaneous wounds on the back of white mice after depilation. We sprayed bidistilled water or physiological serum on the wounds daily, and sketched the scab's contour on tracing paper and then transferred it to millimetered cross-section paper. On the same sketch we measured the length and width of the wound and introduced the data in a statistical program for calculation of its surface area.

Results: One week after initiating the experience, we obtained a wound closure mean favourable to the group subjected to cleansing of same with physiological serum ($P<0{\cdot}0331$). In the second week we achieved very similar wound closure means without statistical significance, regarding the clinical material used for cleansing. The surface areas found did not offer any substantial difference between the calculation of the cutaneous wound's evolution obtained directly and the one obtained by the indirect method.

Conclusions: The use of physiological serum is preferable for cleansing cutaneous wounds to that of bidistilled water, to achieve favourable cicatricial effects during the first week of the healing process.

The use of bidistilled water is recommended after the first week for its similar behaviour and lower cost.

The indirect method gives reliable results in assessing the evolution of the surface area of cutaneous wounds and also shortens the measuring process.

The effects of desmopressin on coagulation system in obstructive jaundice

A. Çökmez, E. Durak, S. Gür, O. Karabağ, S. Deniz and F. Erciyas *1st General Surgery Department and Biochemical Laboratory, Izmir Atatürk Training Hospital*

Purpose: This study was created to show the effects of desmopressin on coagulation system in obstructive jaundice.

Methods: In this experimental study we used forty Wistar Albino male izogenetic rats. We divided them into four different groups. Group 1: Sham laparotomy + Placebo (SC), Group 2: Sham laparotomy + High dose desmopressin (SC), Group 3: Bile duct ligation + Placebo (SC), Group 4: Bile duct ligation + High dose desmopressin (SC).

In all groups we determined the levels of bleeding time, protrombin time (PT), activated partial thromboplastine time (APTT), fibrinogen and factor VIII activity.

Results: We found that bleeding time, PT, APTT have increased, factor VIII and fibrinogen levels have decreased as a result of obstructive jaundice. In groups who received high dose desmopressin, significantly reduced bleeding time and APTT were found. Also factor VIII activities were significantly increased after high dose desmopressin injection. There were no significant changes at PT and fibrinogen levels in desmopressin groups.

Conclusion: Bleeding time, APTT were significantly shortened after high dose desmopressin injection. Factor VIII activity levels were also increased who received high dose desmopressin. High dose desmopressin did not induce any significant changes of PT and fibrinogen. We conclude that desmopressin can positively influence the hemostatic system in patients with obstructive jaundice. The clinical importance of this hemostatic improvement deserves further evaluation.

Detection of gastrointestinal micrometastatic cells in bone marrow by immunocytochemistry and polymerase chain reaction

M. Gabriel, K. Pawlaczyk, P. Chęciński and G. Oszkinis
Department of the General and Vascular Surgery, University of Medical Sciences, ul. Długa 1–2, 61-848 Poznań, Poland

The aim of the study was to detect tumour cells of gastrointestinal carcinomas with the reverse transcriptase polymerase chain reaction and immunocytology in bone marrow.

Methods: We studied 74 patients who underwent surgery for a carcinoma of the colorectum ($n=51$) and pancreas ($n=23$). Cytological samples from peritoneal cavity lavages and bone marrow aspirates were analysed using monoclonal antibodies against tumour-associated antigens (CEA, CA 19-9 and 17-1A) and cytokeratin 18 (CK-2). For RT-PCR we used specific primers for CEA. Specificity of RT-PCR and immunocytology was assessed by examination of 11 negative controls.

Results: The tumour cells were detected by immunocytochemistry in 22 per cent of colorectal and 52 per cent of pancreatic cancer patients. The use of two antibodies (CK-2 and CA 19-9) detected 92 per cent of all positive samples, whereas CK-2 and CA 19-9 stained approximate 70 per cent of all positive samples in each case. In comparison, the RT-PCR method yielded a higher detection rate 36 per cent of colorectal and 61 per cent of pancreatic cancer patients. There was a good correlation between the detection rate and tumour stage regarding all 4 mAbs and RT-PCR: the rate was significantly lower in patients with a tumour in stage I/II in comparison to stage III/IV. The occurrence of stained cells in bone marrow correlated with classical prognostic factors (TNM classification).

Conclusion: Our results show, that PCR amplification of CEA mRNA and immunocytochemical detection of micrometastatic cells in bone marrow are a useful technique.

Establishment of an experimental model of colon cancer which replicates the regional extension pattern of human colorectal adenocarcinoma

D. García-Olmo, M. García-Rivas, D.C. García-Olmo and M. Atiénzar *Experimental Research Unit and Dept. of General Surgery, Albacete General Hospital, Albacete, Spain*

Aim: The aim of this study was to develop an experimental model of colon adenocarcinoma based on the orthotopic implantation of tumour cells in syngenic rats, which reproduces the regional extension pattern of human colorectal adenocarcinoma.

Material and methods: *Cell cultures:* Cell line DHD/K12-PROb. *Animals:* BD-IX rats. *Tumour implantation:* Intra-caecal injection containing 1×10^6 cells in 0·25 ml of PBS. *Design:* Six groups were established according to the moment when the animals were killed: first, second, fourth, sixth, eighth and sixteenth week after inoculation. *Measurements:* Macroscopic and histological examination, with particular emphasis on caecal lesions. Tumours were classified according to the TNM system (UICC, 1987).

Results: Group 1 (animals sacrificed on the first week after inoculation): tumours were found in 90 per cent of cases (9/10), which were classified as $T_1N_0M_0$ and $T_2N_0M_0$; Group 2 (second week): tumour in 36·4 per cent of cases (4/11), classified as $T_2N_0M_0$ and $T_3N_0M_0$; Group 3 (fourth week): tumour in 54·5 per cent of cases (6/11), classified as $T_2N_0M_0$, $T_4N_0M_0$, $T_4N_1M_0$ and $T_4N_2M_1$; Group 4 (sixth week): tumour in 70 per cent of cases (7/10) and were classified as $T_1N_0M_0$, $T_2N_0M_0$, $T_4N_1M_0$, $T_4N_2M_1$ and $T_4N_3M_1$; Group 5 (eighth week): tumour in 100 per cent of cases (10/10) and were classified as $T_1N_0M_0$, $T_3N_0M_0$, $T_4N_0M_0$, and $T_4N_2M_1$; Group 6 (sixteenth week): tumour in 90 per cent of cases (9/10) and were classified as $T_4N_2M_0$ and $T_4N_3M_1$. The 82·2 per cent of the

tumours were localized in the cecum submucosae. The metastases were observed in lung, omentum, kidney, liver, small bowel and timus. Tumour cells were observed in lymphatic vessels in 55·5 per cent of the animals with tumours and in 4·4 per cent of them were observed in blood vessels.
Conclusions: Our model offers a step by step reproduction of events described for human colorectal adenocarcinoma. It was therefore easy to predict how long it would take to achieve a degree of local extension, which is essential in the design of cancer experiments.

Monitoring of evoked potentials during ischemic damage of spinal cord: experimental evaluation in a rabbit model

J.A. Gonzalez-Fajardo, J. Glez.-de-Zárate, J.C. Alvarez,
J.M. Toledano and B. De Andres *Departamento de Cirugia, Facultad de Medicina, Universidad de Valladolid, c/ Ramon y Cajal nº 7, Valladolid 47005, Spain*

Aim: Somasensory evoked potentials (SEPs), spinal evoked potentials (Spinal-Eps), and motor evoked potentials (MEPs) were monitored in a rabbit model of spinal cord ischemia to evaluate their efficacy and to determine the correlation between evoked potentials and clinical status.
Materials and methods: Thirty New Zealand white rabbits of both sexes (2·0 to 3·7 kg) were used for this study. A modified rabbit spinal cord ischemia model of infrarenal aortic occlusion for 21 minutes was employed. After baseline SEPs, Spinal-Eps, and MEPs were obtained, evoked potentials were recorded continuously during and after clamping of the aorta (30 minutes). The animals were placed in cages for neurologic evaluation at 24 hours. Finally, the spinal cord was removed for histologic study. Main outcomes measures: according to the clinical status the animals were graded into two categories: (1) Normal, and (2) Paraplegia. Neurological outcome was correlated with evoked potentials, and histopathological findings.
Results: Fifteen animals were paraplegic. MEPs were always abolished after clamping of the aorta while Spinal-Eps and SEPs still remained. The sensory evoked potentials (SEPs and Spinal-Eps) were the least sensitive to spinal cord ischemia, and their presence had no correlation with the final clinical status (50 per cent of false negatives). This was consistent with the histopathological examination that showed damage almost entirely confined to the anterior horn, while the dorsal columns were generally well preserved. High spine MEPs evoked by twitch stimulation was the best predictor of clinical outcome (0 per cent of false negatives, 0 per cent of false positives).
Conclusions: Our findings confirm the dissociation between the motor and sensory pathways, and that the anterior horn of the spinal cord is more sensitive to ischemia than dorsal columns. Because of this, SEPs and Spinal-Eps cannot be used as safe monitors of ischemia of the spinal cord. High spine MEPs evoked by twitch stimulation is the most useful method for real-time evaluation of spinal cord ischemia, and the best predictor of neurologic outcome during reperfusion.

Different patterns of Tγδ and Tαβ cell redistribution after surgical trauma

A. Gryglewski, M. Szezepanik, P. Majcher, T. Popiela and
W. Ptak *I Dept. of General and GI Surgery CMUJ, 31-501 Kraków ul. Kopernika 40, Polska*

Aim: We observed on mice that the major surgical stress (gastrectomy) may disturb the normal cell traffic selectively with increased T cell homing in intestinal Peyer's patches and lymph nodes (GALT) and with the cell displacement from peripheral blood to lymphatic organs. Present study was performed to compare human reaction after the surgical stress to animal model.
Materials and methods: We investigated the changes in the peripheral blood WBC counts, Tγδ and Tαβ cell number in patients undergoing standard surgical procedures: gastric resection, rectal resection, cholecystectomy, strumectomy. Cells were counted on the FACSTAR cell sorter.
Results: We observed that after procedures on gastrointestinal system the lymphocyte number, especially Tγδ number decreases. Other types of operations that did not affect peritoneal cavity (strumectomy) had much lesser or opposite effect on lymphocyte cell number.
Conclusion: We would suggest that described effect is provoked by homing of lymphocytes in lymphatic organs after surgical stress similarly as we had observed in the animal model.

The use of gentamicin-containing sponges in the prevention of colonic anastomotic leakage in a rat model of peritonitis

P. Lauwers, J. Hendriks and W. Vaneerdeweg *Laboratory for Experimental Surgery, University of Antwerp, Universiteitsplein 1, Building S4, B 2610 Wilrijk, Antwerp, Belgium*

Intestinal anastomoses in a septic environment are considerably at risk. The aim of the present study was to evaluate whether a gentamicin-containing collagen sponge had a beneficial effect on the healing of a colonic anastomosis in a rat model of peritonitis.
Materials and methods: Peritonitis was created in fourty male Wistar rats by intraabdominal implantation of a capsule containing human stools mixed with an equal volume of peptone-yeast-glucose broth, plus 10 per cent barium sulphate. One day later, the descending colon was sectioned transversely and reanastomosed using eight interrupted sutures; randomization into four groups took place (n=10). Animals in group 1 (control group) received no additional therapy. A collagen sponge was wrapped around the anastomosis in group 2. A gentamicin-containing sponge was applicated in group 3 (2·6 mg/cm^2 gentamicin), while gentamicin was administered systemically in group 4 (12 mg/kg intramuscular). Four days later, animals were sacrified. Anastomotic strength was measured while insufflating the descending colon with air at a constant rate; the pressure at the moment of anastomotic rupture ('bursting pressure') was recorded. Results were interpreted using Student's t-test.
Results: Seven animals died of sepsis during the first 24 hours after the anastomosis: two in groups 1 and 2 each, three in group 3. In all groups, a mean weight loss of approximately 25 gram was noted; however, in group 2 (collagen-sponge without gentamicin), mean weight loss was 50 gram (P<0·05). The value of the bursting pressure (SD) was 111 (22) mm Hg in group 3 (gentamicin-sponge), in group 4 (gentamicin systemically) 90 (43) mm Hg and in group 1 (controls) 88 (49) mm Hg (P>0·05). In group 2 (collagen-sponge), bursting pressure was 7 (21) mm Hg (P<0·001 when compared to groups 1, 3 and 4): seven out of eight rats had an open perforation.
Conclusions: Local application of a collagen sponge in an infected environment severely compromises wound healing. Use of a gentamicin-containing sponge does not increase significantly the strength of an intestinal anastomosis in the rat.

Murine and human macrophages respond differently to lipopolysaccharide

D.A. McNamara, G. Pidgeon, J. Harmey, T.N. Walsh,
H.P. Redmond* and D.J. Bouchier-Hayes *RCSI Department of Surgery, Beaumont Hospital, Beaumont Road, Dublin 9, Ireland and *Department of Surgery, Cork University Hospital, Cork, Ireland*

Aims: Exposure to airborne endotoxin (lipopolysaccharide, LPS) during surgery results in increased serum VEGF (vascular endothelial growth factor), the most potent angiogenic factor known, in a tumour-bearing murine model. Our aim in this study was to determine the effect of LPS exposure on VEGF production by murine and human macrophages.
Methods: Peritoneal macrophages isolated from LPS sensitive (HEN) and LPS resistant (HEJ) mice were adhered and stimulated *in vitro* with LPS (1 ng to 100 ng) for 24 hours. Human monocytes were isolated from peripheral blood, matured to macrophages *in vitro* and activated with interferon-γ. They were incubated with LPS (1–100 ng) for 24 hours. VEGF mRNA expression was determined semi-quantitatively by rt-PCR (reverse transcriptase polymerase chain reaction) and VEGF protein levels were determined by ELISA.
Results: VEGF mRNA and protein expression were not significantly altered in LPS-stimulated peritoneal macrophages isolated from LPS sensitive or LPS resistant mice. In contrast, human macrophage VEGF

mRNA expression is increased in response to LPS in a dose-dependent manner.

Conclusion: In the murine model, LPS does not directly elicit VEGF production by macrophages whereas human macrophages demonstrate increased VEGF production following LPS exposure. This finding emphasizes further fundamental differences between murine and human macrophages which are not, as yet, fully explained.

Effect of octreotide treatment on cytokine production in acute pancreatitis in rats

J. Marton, Zs. Szasz, Zs. Nagy*, K. Jarmay**, T. Takacs**, J. Lonovics, A. Balogh and Gy. Farkas *Department of Surgery, *Department of Microbiology, **First Department of Medicine, Albert Szent-Gyorgyi Medical University, P.O.B. 469, H-6701 Szeged, Hungary*

Aim: To determine the effect of octreotide treatment on the cytokine production in acute necrotizing pancreatitis in rats.

Methods: Acute pancreatitis was induced by the retrograde injection of taurocholic acid into the pancreatic duct in male Wistar rats. The serum amylase activity, the wet pancreatic weight/body weight ratio, and the TNF and IL-6 levels were measured. Four µg/kg octreotide was administered subcutaneously at the time of induction of pancreatitis and 24 or 48 hours later. Rats were sacrificed 6, 24, 48, 72 hours after the operation.

Results: Serum amylase levels and pancreatic weight to body weight ratio decreased significantly ($P<0·05$) in the octreotide-treated group. Serum TNF levels decreased significantly in the octreotide-treated group as compared to the control group at 6, 24 and 48 hours (0·57±1·51 U/ml; 2·0±3·34 U/ml, 0 U/ml versus 50±15·49 U/ml; 37·5±18·37 U/ml; 13·125±12·51 U/ml, respectively).

Conclusions: Octreotide has a major influence on the cytokine production in sodium taurocholate-induced acute necrotizing pancreatitis in rats. Due to its complex effect octreotide can partially ameliorate the deleterious consequences of acute necrotizing pancreatitis. Elevated cytokine levels of the peritoneal fluid may be explained by the activation of peritoneal macrophages.

Protective role of truncal vagotomy in stress ulcer in short, medium and long term

S. Rodríguez, A.M. Bayón, J.M. Alcalde, I. Vegh, L. Ortega, E. Rodríguez, I. Landa and J.L. Balibrea *Hospital 12 due Octubre, Madrid, Spain. Mailing address: (Dra. Silvia Rodríguez): c/ Jaime el Conquistador 13, portal 2–8ºC, 28045 Madrid*

Introduction: Usefulness of truncal vagotomy in ulcer disease is more and more restricted because it does not seem to control the mediators of gastric acid secretion (gastrine, histamine) in long term. Nowadays, its indications seem to be limited to those complications directly related to cholinergic way (mainly those related to stress).

Aim: To assess the protective role of truncal vagotomy in short, medium and long term in animals under stress.

Materials and methods: Eighty Wistar rats were operated: truncal vagotomy, pyloroplasty and Heller's esophagic myotomy. We established four groups with 20 animals in each one, in relation to postoperative period before their sacrifice: A (long term) 120 days, B (medium term) 30 days, C (short term) 7 days and D (control, non-operated). Before they were sacrified, 10 rats in each group were under stress and we subsequently assessed gastric bleeding and erosive mucosal lesions. We also measured pre and postoperative gastrinemia levels with and without stress.

Results: Eight of 10 animals under stress in group D had gastric bleeding and erosions but only two in group C and one in groups B and A. Gastrinemia levels were worthless.

Conclusions: Our results point out that truncal vagotomy seems to protect from stress ulcer in short, medium and long term in Wistar rats.

We know about the variations of hormonal mediators of gastric acid after vagotomy in rats (double increase of G cells hyperplasia in short and long terms)[1] so we can suspect that the main mediator of stress is the acetylcholine and not gastrin. In this way, truncal vagotomy could still be in use to treat stress ulcers.

[1] Landa JI, Alcalde J, Yuste P, Ortega L, Ramia JM, Carrillo A, Balibrea JL. Influencia de la vagotomia troncular sobre las células G y D en el antro gástrico del cobaya. Cir Esp 1995; 58(3): 212–215.

An improved method for producing hepatic cirrhosis in rats

M.A. Secchi, E. Tagliaferri, E. Peralta, J. Monti, L. Quadrelli, L. Rossi and L. Lambotte *Unit of Surgical Research, Hospital Italiano de Rosario (Argentina) and Experimental Surgery Laboratory, University of Lovain, Medical School (Belgium) Riobamba 524, (2000) Rosario, Argentina, Fax 54-41-811049*

Many models of carbon tetrachloride (CCL4) induced liver cirrhosis in the rats have been described. Nevertheless reproduction and persistence of cirrhosis is still hard to obtain.

Methods: Cirrhosis was produced in three rat series since 1988 (n=79) by a nine-week period of combined subcutaneous and gastric administration of CCL4. CCL4 was given once a week by intragastric route in doses increasing from 0·05 ml to a 0·40 ml maximum, adapted to the change in body weight. In addition, CCL4 dissolved in 50 per cent mineral oil was given once a week. A subcutaneous dose of 0·2 ml/150 g/body weight three days after the intragastric administration was given. The presence of ascitis, serum levels of albuminemia, bilirubinemia and ASAT were recorded and compared with a control group. Histological examination was made to confirm the cirrhotic state at two weeks, and at two and five months after the end of CCL4 administration. A control series (n=8) given only water was used for statistical analysis by Student's t-test.

Results: Thirty-three out of 79 rats (42 per cent) were alive at the end of the procedure. Histological evidence of micronodular cirrhosis was confirmed in 31 of 33 (94 per cent). Ascitis was 3·8±0·6 ml and 0·00 ml in control group (n=8) ($P<0·001$). ASAT was 251±107 U/l and 84±9 U/l in the control group ($P<0·01$). Albuminemia was 2·08±0·6 mg per cent and 2·84±0·4 in control group ($P<0·05$). Bilirubinemia was 1·22±0·28 mg per cent and 0·16±0·05 in control group ($P<0·001$). Twenty-four out of 31 cirrhotic rats survived for two months and 12 of those 24 survived for five months, all of them with histological evidence of cirrhosis.

Conclusion: We described and adapted a CCL4 induced cirrhosis model with 94 per cent of improvement. 77 per cent of the cirrhotic rats survived two months and 38 per cent five months with histological evidence of micronodular cirrhosis. This model is easy (18 doses), fast (nine weeks), efficient (94 per cent) and stable after five months in surviving rats.

Interleukin-1β (IL-1β) effect on polymorphonuclear neutrophil tissue-accumulation after endotoxic injury

L. Telles, A. Mansilla, J.A. Ferrón, A. Collado, R. Lupiani and M.J. Vilchez *Unidad de Cirugía Experimental, Hospital 'Virgen de las Nieves', Avda. Fuerzas Armadas, nº 2, 18014 Granada, Spain*

Introduction: Systemic Inflammatory Response Syndrome (SIRS) is mediated by the activation of multiple immunologic mediators. During SIRS there is a sequestration of leukocytes in the endothelial cells in different organs. In this study we investigate the effect of the pretreatment with IL-1β on tissue leukocyte infiltration after experimental endotoxic challenge.

Materials and methods: Seventy-two female CBA/H mice, 10–12 weeks old, were divided into three groups of 24: Group 1 = Sham (normal values); Group 2 = Endotoxic shock was induced by LPS from *Escherichia coli* serotype O55:B5 125 mg/kg intraperitoneally (i.p.); Group 3 = Pretreated with IL-1β 80 ng/mouse injected i.p. 24 hours (hr) before LPS. At 1, 2, 4 and 24 hr after LPS, the animals were killed and the liver, lungs and small intestine removed (six mice per hr and group). Tissue leukocyte accumulation in the different organs was evaluated by measurement of the products derived from leukocyte degranulation (myeloperoxidase (MPO))

by spectrophotometry. Values of MPO are expressed in U/mg of protein. Differences in mean values of MP at different times were compared using Newman-Keuls's test.
Results: *Liver:* We observed a decrease in MPO levels at 24 hr in group 3 in relation to group 2. *Lung:* There was no difference between groups. *Intestine:* MPO levels increased at 1, 2, 4 and 24 hr in group 3 in relation to group 2.
Conclusions: Pretreatment with IL-1β increases the leukocyte accumulation in small intestine after endotoxic challenge. In advanced stages after the aggression the leukocyte accumulation decreases in the liver, while the lung is not affected.

Dietary fibre. The effects on experimental colonic anastomoses

A. Vázquez, F. Villalba, E. Artigues, M.J. García-Coret, J. Aznar and E. Montalvá *Service of General and Digestive Surgery, Valencia University General Hospital, Valencia, Spain*

Aim: Different dietary fibres (low fiber, LF; low fibre with pectin, LFP; low fibre with karaya, LFK; standard rat chow, SD) were used to study fecal bolus effects upon the cicatrization of colonic anastomoses in rats.
Material and methods: Fifteen rats were included in each dietary group. Anastomotic cicatrization was evaluated in terms of the complications observed, bursting pressure (BP), histology, and the quantification of hydroxyproline. To this effect, a segment of colon was removed, followed by end-to-end anastomosis. The rats were reoperated after seven days, removing the colon segment containing the anastomosis. Both segments were compared in each group, and between groups.
Results: Fecal bolus weight was significantly modified in all groups, and was greatest in the SD and LFK groups, which presented more anastomotic complications. BP (mm Hg) in the intact colon (control) was greater in the SD and LFK groups (214·2±7 and 197·3±7, respectively), significant differences being observed between the SD and LFP (174·2±7) groups. BP on reintervention (day 7) was greatest in the LFP group (193·9±7), with significant differences vs the LF and LFK groups (155·5±9 and 154·2±1, respectively). Bursting wall tension (BWT) (kdynes/cm) in the controls (day 0) was significantly lower in the LF and LFP groups (50·7±2·9 and 59·5±3·4, respectively) than in the LFK and SD groups (84·7±4·1 and 91·3±3·5, respectively). In turn, anastomotic BWT (day 7) was lower in the LF group (48·2±3·2) than in the animals given pectin (65·9±3·4), karaya (66·7±4·8) and standard diet (80·3±4·8) ($P<0{\cdot}01$). Collagen concentration in the control colon was greater in the LF diet vs the other three groups ($P<0{\cdot}07$). In the colonic anastomoses the collagen contents were significantly lower than on day 0, though no intergroup differences were observed. The histological study likewise revealed no significant differences.
Conclusions: Lower fibre diets reduce the basal pressure parameters of the colon, though without affecting subsequent gains in anastomotic resistance. In turn, the improved cicatrization observed when supplementing a low fibre diet with pectin is no longer apparent when each animal is used as its own control.

Intestinal sutures in the rat: preliminary results

C. de Werra, P. Marra, A. Marano, F. D'Armiento* and P. Forestieri *University of Naples 'Federico II', Surgical and Oncological Department: Chief Prof. P. Forestieri, *Institute of Pathology: Chief Prof. R. Vecchione, S. Pansini St. n° 5, 80131 Naples, Italy*

One of the most important clinical advances in suture technology was the development of synthetic absorbable sutures to replace gut sutures. The role of a suture, in fact, is to realize an approaching of two ends of a continuum solution until the wound acquires enough mechanical strength. The ideal situation would be that the material disappears once the wound is sufficiently resistant, and that the utilized suturing material has a least impact on the healing process. Authors evaluate and compare the effectiveness of five synthetic absorbable sutures to other four different absorbable synthetic sutures in intestinal anastomes in the rats, as well as their impact on the normal wound healing physiopathological process. The experimental work has been performed on three groups of six rats, sacrificed after 6, 20 and 90 days respectively. The preliminary anatomopathological results show that the least interference is given by the Glycomer* 631 and the polyglycolic acid, polyglyconate gives good results, but brings a greater fibrous reaction. At a lower level polydioxanone and polyglactin acids are found, with slightly better results for the former. The evaluation of surgical characteristics has allowed the materials to be classified into three categories: one, where features like smoothness and elasticity prevail (polyglyconate and polydioxanone); another, where knot tying and knot resistance and memory are the major characteristics (Poliglycole, Polyglactin); the last class, Glycomer* 631, was significantly stronger than the braided synthetic absorbable suture and the other synthetic monofilament over the three months of implantation and it has the best surgical characteristics because it collects the best of the monofilament and braided sutures.

Retrospective study on 407 laparoscopic cholecystectomies converted to open surgery

L. Angrisani, F. Corcione, A. Tartaglia, A. Tricarico, F. Rendano, R. Vincenti, M. Lorenzo, A. Aiello, C. Bellucci, D. Bruni, F. Caracciolo, D. Cattaneo, G. Chiacchio, L. Cioffi, L. Cobellis, G. Conzo, F. Crafa, A. De Falco, G. De Sena, C. De Werra, R, D'Errico, P. Di Palma, L. Docimo, F. Frega, C. Giardiello, V. Landolfi, C. Mazzarella, O. Micera, O. Petrillo, R. Rea, G. Rispoli, P. Smaldone and P. Sperlongano *Lap Club – Coll. Study Group, c/o Fondazione IDIS, via Coroglio, 156-80124 Naples, Italy*

Aims: Retrospective analysis of causes of conversion to laparotomy during laparoscopic cholecystectomy and type of incision performed.
Methods: A questionnaire was mailed to all surgeons independently working in Naples and its neighbouring area with experience of >100 laparoscopic cholecystectomies. Data were collected for patients converted to open surgery from February 1990 to November 1997. Twelve thousand seven hundred and eighteen cholecystectomies were performed by 33 surgeons.
Results: Four hundred and seven (3·2 per cent) patients were converted to open laparotomy. Causes of Conversion Not Related (CNR) to laparoscopic cholecystectomy have been 27 (6·6 per cent). CNR were: diagnostic failure (n=7; 25·9 per cent); equipment failure (n=9; 33·3 per cent); complications of pneumoperitoneum (n=11; 40·8 per cent). In this group one patient died (0·3 per cent) by Veress needle vascular injury. Causes of Conversion Related to laparoscopic cholecystectomy (CRC) have been 380 (93·4 per cent), and were: adhesions (n=180; 47·6 per cent) non-dissectable Calot triangle (n=76; 20 per cent) biliary and vascular anatomical variations (n=10; 2·5 per cent) advanced acute and chronic inflammations (n=25; 6·7 per cent); common bile duct lithiasis (n=19; 5 per cent); gallbladder cancer (n=11; 2·8 per cent); complications during surgical dissection (biliary: 23, 6 per cent; vascular: 36, 9·4 per cent). Mortality was absent in this group. Laparoscopic time before laparotomy has been 30±10 minutes (range 7–150). Laparotomy has been performed by subcostal access in 314 (77·1 per cent) patients, 85 (27·1 per cent) of these were minilaparotomies. In the remaining a midline incision was preferred. Laparotomics were complicated in 38 (9·3 per cent) cases, four of whom (10·5 per cent) required subsequent laparotomy.
Conclusion: Collected experiences of causes, timing, type of incision and morbidity of laparotomic conversion during laparoscopic cholecystectomy, still represent an area of concern. Regional audit is very useful and is definitively needed specially for surgeon starting laparoscopic approach or at the beginning of their surgical experience.

Second-look endoscopy with repeated injection of thrombin with adrenaline vs fibrin glue in bleeding peptic ulcer

A. Babicki, M. Dobosz, R. Marczewski and Z. Wajda *II Department of General, Gastroenterological and Endocrinological Surgery, Medical University of Gdańsk, 1, Prof. Kieturakis Street, 80-742 Gdańsk, Poland. Tel/Fax 04858 3018775*

A prospective randomized study was conducted to assess whether a repeated injection of fibrin glue is superior over repeated thrombin/adrenaline injection.

Thirty patients with bleeding peptic gastric or duodenal ulcer (Forrest Ia or IIa) were divided into two groups, 15 patients each. In all the patients initial injection therapy with thrombin/adrenaline was used. In Group I repeated injection with thrombin/adrenaline solution and in Group II with fibrin glue (Beriplast) was performed. In four patients (26·6 per cent) of the group I (reinjection with thrombin/adrenaline) recurrent bleeding was observed. Three patients were successfully injected again, in one patient emergency gastric resection was carried out. In the group II, the authors observed one recurrent bleeding (6·6 per cent), effectively treated with repeated endoscopic injection. The mean hospital stay of the bleeding patients in the group I was 13·2 days (5–50 days), and in the group II 7·4 days (4–12 days). No mortality and complications were observed due to the applied treatment.

Summarizing, our results suggest a possibility of benefit with the second-look elective endoscopy and repeated injection of fibrin sealant.

Diagnostic laparoscopy in suspected dissemination of intraabdominal neoplasms

A. Budzynski, A. Bobrzynski, M. Winiarski, W. Kostarczyk and J. Krzywoń *2nd Department of General Surgery, Collegium Medicum of Jagiellonian University, ul. Kopernika 21, 31-501 Krakow, Poland*

Intraabdominal dissemination of cancer into parietal peritoneum, omentum or liver surface except for very rare cases could not be diagnosed preoperatively. Some data like marked weight loss, ascites and others based only on weak, poorly documented suspicion might suggest the widespread disease. Unfortunately non-invasive methods that would allow for diagnosis of peritoneal spread are currently not available. Without preoperatively confirmed dissemination laparotomy with curative intention is in these patients usually attempted but in many cases even this results in big trauma for those patients. Postoperative period is long-lasting and complications are likely to occur. We believe, that low trauma associated with laparoscopy resulting in smooth and in most cases uneventful postoperative period justifies its use in those cases. Following this at the 2nd Department of General Surgery we performed diagnostic laparoscopy in 18 patients with suspected disseminated cancer. In eight of them dissemination was confirmed without identification of the primary tumour. In five pelvic mass originating from adnexa was discovered, in three the primary tumour was located in the gallbladder, two in pancreas, one in the stomach. In each case we were able to obtain samples for pathological examination. We observed no complications related directly to the procedure. Patients received normal oral diet in the 2–3 postoperative days and went home 4–7 days after operation. Laparoscopy with its obvious advantages of minimal invasiveness allowed us to make precise diagnosis and unnecessary laparotomy was avoided.

Emergency laparoscopy in acute abdomen

A. Budzynski, A. Bobrzynski, W. Kostarczyk, J. Krzywoń and M. Winiarski *2nd Department of General Surgery, Collegium Medicum of Jagiellonian University, ul. Kopernika 21, 31-501 Krakow, Poland*

Laparoscopy with its minimal invasiveness, ability to precisely delineate diagnosis and in many cases possibility to perform final treatment is a new, promising tool in the hands of a surgeon dealing with abdominal emergencies. Low trauma associated with this procedure, short hospitalization and ability to regain normal activity within a short period of time are obvious advantages appreciated by patients. The method itself is more demanding than in elective case with precise preoperative diagnosis and requires considerable experience. The access to some organs is difficult as well as handling of friable, inflamed tissues often covered with blood, pus or debris. Taking into account the limitations of the method we believe that it could be offered to most of patients with 'acute abdomen'. At our department we performed 102 emergency laparoscopies; 16 cases of laparoscopy for abdominal trauma are excluded as they were subject to another report. We present 86 patients with 'acute abdomen' submitted to laparoscopic procedure. Preoperative diagnosis that led to the operation were as follows: appendicitis 64, ileus 7, peritonitis 7, perforated ulcer 4, pancreatitis 4. In 82·5 per cent (66 of 80) patients requiring operative management the final treatment was performed laparoscopically, in 14 (17·5 per cent) conversion to an open procedure was necessary. In six (6·97 per cent) patients no pathology requiring surgical treatment was found. In those patients unnecessary laparotomy has been avoided. In eight (9·3 per cent) cases the diagnosis was different than preoperative but requiring surgery was undertaken during laparoscopy and patients were submitted to appropriate treatment. Four of them required conversion and laparoscopy allowed for choosing proper access for open procedure. Our experience confirms well known facts that laparoscopy in abdominal emergencies gives a chance to define precisely diagnosis, perform in most cases final treatment and to reduce the number of unnecessary laparotomies. Even though the procedure is difficult, requires trained staff and expensive equipment it should be strongly recommended.

Extraperitoneal endoscopic nephrectomy using pneumoretroperitoneum under coelioscopic control

L. de Cannière, F. Lorge and L. Michel *Mont-Godinne University (UCL) Hospital, B-5530 Yvoir, Belgium*

Aim: The extraperitoneal approach is a logical access for nephrectomy with a posterior access to the renal pedicle without interference with intraperitoneal organs. We show a right retroperitoneoscopic nephrectomy (multicystic kidney) under coelioscopic control using a direct pneumoretroperitoneum.

Material: Patient is placed in the lateral decubitus position. A Veress needle is introduced at the level of the lumbar triangle in the retroperitoneal space, that is insufflated with CO_2 (12 mmHg). Development of the pneumoretroperitoneum is watched by an optic inserted via an intraperitoneal paraombilical trocar. The retroperitoneal space created by the pneumoretroperitoneum can easily be widened by blunt dissection with a 10 mm diameter coaxial laparoscope inserted through a trocar placed in the lumbar triangle. Under intra and extraperitoneal control, three other retroperitoneal trocars are then safely introduced. The pneumoperitoneum is then exsufflated in order to allow the pneumoretroperitoneum to further enlarge. The ureter after being clipped and sectioned is pulled up to visualize the hilum of the kidney. The renal artery is first controlled by clips before ligation of the vein. The nephrectomy is completed by dissection of its upper role and anterior face. The kidney is extracted in a plastic bag.

Results: This technique was applied to six patients (right/left: 3/3) for hydronephrotic kidneys (15 to 20 cm), two multicystic and one atrophic post nephritis kidneys. The mean operative time was 200 minutes and there was no blood loss. Increase of $PaCO_2$ above 44 mmHg was recorded in one patient. There was no complication.

Conclusion: The retroperitoneoscopic nephrectomy is safely feasible. The extraperitoneal working space is large enough and the intraperitoneal control avoids blind injury to intraperitoneal organs.

Gasless laparoscopic and local anesthesia in high risk patients

A. Cano, M. Diaz, S. Morales, A. Gonzalez, R. Pérez-Huertas and M. Martin *Laparoscopic Surgery Unit, Virgen Macarena Hospital, Avenida Doctor Fedriani n° 3, 41071 Sevilla, Spain*

Introduction: Metabolic changes associated with pneumoperitoneum are usually of little clinical significance in healthy patients but may adversely affect the outcome in patients with underlying cardiac or respiratory disease. The gasless laparoscopic method using an electric lift introduced into abdominal cavity avoid the physiopathological problems of the pneumoperitoneum and perform a safe alternative in patients with a compromised respiratory or cardiac status.

We present abdominal explorations using local anesthesia and gasless method in patients with important pulmonary or cardiac dysfunction.

Materials and methods: We performed gasless laparoscopic surgery and local anaesthesia under direct vision in three patients (age 65, 77 and 81). All patients presented serious pulmonary dysfunction.

Results: We found one abdominal infection and observed two intestinal tumour. This method permitted to do some biopsies and tumour staging without any complications.

Conclusions: Gasless laparoscopic surgery with local anesthesia represents may provide a safer alternative method of exposure for minimally invasive surgery in patients with a compromised respiratory or cardiac disease.

Gasless laparoscopic in abdominal surgery: an early experience

A. Cano, M. Diaz, S. Morales, A. Gonzalez, A. Pérez-Sanchez and M. Martin *Laparoscopic Surgery Unit, Virgen Macarena Hospital, Avenida Doctor Fedriani n° 3, 41071 Sevilla, Spain*

Introduction: The abdominal wall lifting or gasless method presents important advantages when compared to the traditional pneumoperitoneum method. Since all operative procedures are performed under normal pressure, the complications caused by pneumoperitoneum can be avoided and, at same time, unlimited suction and irrigation can be obtained without a reduction of exposure. In addition, simple valveless trocars and conventional surgical instrument can be used.

In this communication we summarize our first experience of using gasless laparoscopic in abdominal surgery and we present the potential advantages of this technique.

Materials and methods: We performed gasless laparoscopic surgery in 20 patients: cholecystectomy (n=11), abdominal exploration and biopsy (n=3), appendectomy (n=2) and others (n=4).

We evaluated physiological effects during anesthesia, postoperative nausea and vomiting, abdominal pain and global cost.

Results: The results obtained are similar to pneumoperitoneum method, but it has been observed a global reduction of costs, less postoperative nausea, vomiting and right shoulder pain, and no cardiovascular and metabolic disturbances. We observed one wound infection as complication and two times we had to change the surgical procedure.

Conclusions: Gasless laparoscopic surgery seems to be a reliable alternative to conventional laparoscopic and demonstrate potential advantages for selected indications.

Laparoscopic fundoplication (LF): results in the first 31 patients and influence of the learning curve

S. Contini, A. Franzé*, R. Dalla Valle, A. Bertelè* and R. Zinicola *Istituto di Clinica Chirurgica Generale e dei Trapianti d'Organo, *Gastroenterology Department, University of Parma, Via Gramsci 14, 43100 Parma, Italy*

Aims: LF has been considered a good alternative to open surgery for gastro-oesophageal reflux disease. We analyse our early experience of LF with a particular attention to the learning curve.

Materials and methods: LF was attempted in 31 patients for medically unresponsive GORD (29 patients) and giant slipping hernia (two patients). Mean age was 38 yrs (23–68), 16 patients were male (51 per cent). A 360° fundopilcation was constructed in 30 cases; a 270° posterior fundopilcation in one case. Short gastric vessels section and suture of the hiatus were not routinely performed.

Results: Mean operative time was 135 minutes but was strikingly reduced from the first (170 minutes) to the second half (100 minutes) of the patients. Seven patients (21 per cent) were converted to open surgery (both patients with giant hernia). Conversion was not observed in the last 15 patients operated for GORD. A delayed gastric wall perforation was observed near a stitch of the gastric wrap (3·2 per cent). Transient (three months) dysphagia was observed in 14 patients (45 per cent), requiring open reoperation in one case (3·2 per cent). Mortality was nil. Recurrency of symptoms is present in two (6·5 per cent) cases (mean follow-up: 17 months – range: 1–40) and appeared two and four months after surgery. Twenty-eight patients (90·3 per cent) are satisfied of the results and would repeat surgery. Both patients with recurrency were in the first half.

Conclusions: The 'learning curve' plays a great role in the first results after LF. Operating time is obviously reduced with the experience. Moreover complications or recurrency of symptoms were not observed in the second half of the patients and conversion in the last 17 cases was necessary only in two patients with giant slipping hernia. Transient dysphagia is common after LF, even in floppy procedures. Section of the short gastric vessels and posterior crural suture have no influence on it in our experience. LF has been demonstrated feasible and safe as open surgery but the analysis of the results of a single surgeon must probably exclude the first phase of experience.

Influence of laparoscopic and traditional cholecystectomy on patients respiratory efficiency

M. Dancewicz and J. Kowalewski *The First Surgical Department of the Military Medical Academy in Lodź, Poland, ul. S. Zeromskiego 113, 90-549 Lodz, Poland, E-mail: wam1klch@polbox.com*

Aim: The aim of the study was to evaluate the pulmonary function test results in patients after standard and laparoscopic operations in the first two days after surgery.
Material and methods: Seventy-six patients treated for cholecystolithiasis in the clinic between 13th June and 30th November 1995 were analysed. The patients qualified for cholecystectomy were divided into two study groups. Group I (55 patients) qualified for cholecystectomy by laparoscopic technique, group II (21 patients) operated on in a traditional way. One day before operation all the patients underwent spirometric examination by means of computer spirometer 'Pneumoscreen II Jaeger Germany'. Vital capacity (VC), exhale reserve volume (ERV), forced vital capacity (FVC) and breathing reserve (BR) was calculated and arterial blood acid-based equilibrium was determined. One and two days after cholecystectomy and the same measurements were repeated in all the patients.
Results: Spirometric results showed diminished VC, FVC and BR first day after operation of 25 per cent in the patients operated on by laparoscopic technique and of 40 per cent in the group operated on in a traditional way. The recovery of those parameters to the preoperative values was slower in patients from group II. Deficiency of breath capacities two days after surgery amounts to 13 per cent in laparoscopic and 30 per cent in traditional method group respectively. All differences in the results of spirometric study were statistically significant. There was no statistically significant changes in arterial blood acid based equilibrum.
Conclusion: The results of the study suggest that laparoscopic cholecystectomy impairs breathing sufficiency of the operated patients to a lesser extent and for a shorter time span compared to a traditional cholecystectomy.

Effectiveness of laparoscopy in case of acute lower abdominal pain in female patients

J. Gardovskis, A. Martinsons and Z. Narbuts *Department of Surgery, Medical Academy of Latvia, Dzirciema Str. 16, LV1007 Riga, Latvia*

Acute Lower Abdominal Pain (ALAP) in females usually can be a problem in everyday practice.
Aim: Aim of the study was to evaluate effectiveness of laparoscopy based diagnosis and treatment algorithm in case of ALAP on young females.
Materials and methods: The criteria for the algorithm were ALAP, sex (females), fertile age (18–45), possible laparoscopy. Targets for following steps were: 1) making the decision to perform laparoscopy by screening examinations, necessary consultations by another specialist; 2) the diagnostic laparoscopy; 3) operation (laparoscopical or open); 4) making the final diagnosis on previous findings or performing another examinations. Laparoscopical findings, laparoscopical operations, histopathological findings, rate of negative appendectomy were analysed prospectively. From September till December 1977, 43 laparscopic procedures on the research group were performed.
Results: In most cases the screening tests and specialist consultation did not prescribe true diagnosis. Laparoscopical findings were: visually inflamed appendix – 21 cases, free liquid in peritoneal cavity – 7 cases, pelvic adhesions – 5 cases, ovarian cyst in 3 cases, polycystic degeneration of the right ovarium – 2 cases, torsion of ovarian cyst with intra-abdominal haemorrhage – 1 case and no visual findings of the disease – 4 cases. Following laparoscopic procedures were performed: laparoscopic appendectomy – 20 cases, aspiration of free liquid – 7 cases, laparoscopic lesion of adhesions – 5 cases, ovarian cyst resection in 4 cases, only diagnostic procedure – 4 cases, electrodestruction of the ovarian cysts – 2 cases, open appendectomy – 1 case. Postoperative histopathological findings (n=25) were: destructive appendicitis – 18 cases, ovarian cyst – 4 cases, catharal appendicitis (negative appendectomy) – 3 cases. Negative appendectomy rate decreased from 32·7 per cent to 7 per cent.
Conclusions: Introduction of laparoscopy based diagnostically and treatment algorithm in case of ALAP on female patients can be method of choice for differential diagnostics and treatment.

The effect of endoscopic retrograde cholangiopancreatography (ERCP) to laparoscopic cholecystectomy

U. Gozalan, M. Doganay, T. Coskun, A.Z. Akat, M. Guler and N.A. Kama *Ankara Numune Hospital, 4th Department of Surgery, Turkey*

Introduction: Although it has a short history, laparoscopic cholecystectomy takes the place of conventional cholecystectomy in the treatment of symptomatic cholelithiasis cases. The morbidity and mortality of this procedure were noted in many studies. According to the studies the most prominent cause of conversion to open surgery is excessive inflammation and undetermination of the anatomy. It has been stated that preoperatively performed ERCP was a minor risk factor in laparoscopic cholecystectomy. We evaluated the impact of ERCP in our 715 laparoscopic cholecystectomy cases.
Patients and methods: Between March 1992–November 1997, 715 laparoscopic cholecystectomy cases were reviewed retrospectively. Patients were grouped according to age, sex, type and the duration of symptoms, previous operations, preoperative evaluation methods and procedures. The duration of the operation, intraoperative complications, postoperative morbidities and mortalities, duration of the hospitalization time were all analysed. We have operated all ERCP performed patients 24–48 hours after that procedure. Statistical analysis was done by using Chi-square (Pearson) test.
Results: Of 715 cases, 30 (4·2 per cent) patients were performed ERCP preoperatively. Eleven of these patients (36·7 per cent) were males and 19 (63·3 per cent) patients were females. Twenty-three patients (76·7 per cent) were above 65 years old and seven (23·3 per cent) were below 65 years. Patients were operated due to chronic calculous cholecystitis in nine cases (30·0 per cent), acute calculous cholecystitis in nine cases (30·0 per cent), cholecystocholodocholithiasis in nine (30·0 per cent) and gallstone pancreatitis in three (10·0 per cent). One patient (11·1 per cent) had undergone upper abdominal operations and eight patients (88·1 per cent) lower abdominal operations previously. In the 27 patients (90·0 per cent) the operation was completed laparoscopically, whereas in three patients (10·0 per cent) the operation was converted to open surgery. The conversion rate was 10·0 per cent. Indications for conversion to open laparotomies were as follows: in two cases (66·6 per cent) due to excessive inflammation and undetermination of the anatomy; one case (33·4 per cent) suspicion of common bile duct injury. This took 60 minutes in 21 cases (70·0 per cent), and in nine cases (30·0 per cent) it was found to be above 60 minutes. The learning curve was accepted as 10 operations per surgeon. According to this 22 patients (73·3 per cent) were operated by the experienced surgeons and eight patients (26·7 per cent) by the inexperienced surgeons. Intraoperative major complications were seen in one case (3·3 per cent) and minor complications were seen in five cases (16·7 per cent). There was no complication in any case postoperatively. Postoperative hospital stay was one day in 22 (73·3 per cent), longer than one day in eight cases (26·7 per cent). Mortality rate was found to be zero.
Conclusion: There were no statistically signficance in patient age, sex, conversion to open procedure, intraoperative and postoperative complication, postoperative morbidity and mortality and duration of postoperative hospitalization. According to our results, we suggest that laparoscopic cholecystectomy can be performed confidently 24–48 hours after ERCP procedure.

Laparoscopic adjustable silicone gastric banding – first experience in Slovakia

P. Holéczy, J. Payer Jr., J. Malina, P. Novák and A. Králová *Railway Hospital, Šancová 110, 832 99 Bratislava, Slovakia*

Aim: To report on the first two cases in whom the laparoscopic adjustable silicone gastric banding system was used. The indication was morbid obesity.

Material and methods: First two operations were done in our institution in December 1997. The patients body mass index (BMI) was 47 and 38. Details of the procedure are described

Results: Both procedures were done successfully In the first case haemorrhage from the port side was observed, this caused prolongation of the operation to more than 4 hours The second one was done in 2 hours 20 minutes Postoperative course was uneventful and patients were discharged on 7th and 5th postoperative day

Conclusion: Surgical treatment of morbid obesity is the last resort for many patients. Laparoscopic adjustable silicone gastric banding according to the literature seems to be very effective operation with very low complications and mortality rate. Our first experience is encouraging

A modified laparoscopic technique of banded vertical gastroplasty for morbid obesity

A. Ingelmo-Setien, C.F. Escalante and E. Martino *Sierrallana Hospital, Valdecilla University Hospital, Cantabria, Spain*

The surgical treatment of morbid obesity has become routine clinical practice Procedures that reduce gastric capacity and dietary intake are now considered preferable to those that alter food absorption as they are associated with fewer side-effects. After a training period in an animal laboratory setting, it was decided to perform a modified banded vertical gastroplasty with vertical section by a laparoscopic approach.

Surgical technique: With the patient under general anaesthesia, the surgeon stood between the patient's legs Five cannulas were distributed in the upper abdomen First the gastrohepatic ligament is opened close to the lesser curvature of the stomach 5–6 cm below the cardias and medial to the gastric vessels Afterwards the His angle is open and a vertical partition of the stomach down 5–6 cm, by using linear articulated is performed A retrogastric tunnel joining both dissected areas was created by blunt dissection under direct vision The output of the neogastric pouch is calibrated on a nasogastric tube by sintetic band of 5 cm long.

Results: In 1997, six morbidly obese patients were treated by this laparoscopic approach All patients were women with a mean age of 28 (range 20–46) years Mean body-weight was 128 (105–146) kg. Mean operating time was 200 (150–240) min

Conclusions:

1 A laparoscopic approach has obvious advantages for morbidly obese patients

2 This modified laparoscopic procedure seems to provide the same results as open technique banded vertical gastroplasty

Laparoscopic truncal vagotomy

F. Karvelas, N. Apostolopoulos and P. Dimopoulos *General Hospital of Patras 'Agios Andreas', Tsertidou 1 26 226 Patras, Greece*

This report presents the technique and results of laparoscopic bilateral truncal vagotomy with or without pyloric dilatation.

Laparoscopic truncal vagotomy was performed in seven patients with chronic duodenal ulcer resistant to medical treatment

We also routinely perform pneumatic dilatation of the pylorus to avoid problems with gastric emptying after a truncal vagotomy in patients with pyloric stenosis.

A flexible gastroscope is positioned within the pylorus and performed lysis of adhesions if it is necessary laparoscopically

The results of acid secretory tests and endoscopic control were studied.

A laparoscopic approach to truncal vagotomy was performed with a mean operation time of 65 min providing low morbidity and early recovery Semiliquid diet was given in early postoperative period (24 hours after operation) and prokinetic drugs were given routinely The patient is discharged 48–72 hours after vagotomy The ulcer healed without gastric stasis as compared with the endoscopic controls at third and sixth month postoperatively Acid secretion (BAO and PAO) was reduced by 80 per cent One of our patients has had moderate diarrhoea which resolved spontaneously

Laparoscopic truncal vagotomy is a simple safety and efficient procedure with low morbidity and early recovery for the management of chronic duodenal ulcer in a group of selected patients

Comparison of different approaches for trocar placement in laparoscopic surgery

F E Klee, B.R. Osswald and St. Wysocki *Dept. of Surgery, Salem Academic Hospital, Zeppelinstr. 11–13, D-69121 Heidelberg, Germany*

Aim: Different approaches of first trocar placement are currently used Even so called, 'safety-trocars' are established in laparoscopic surgery After penetration of the trocar's tip, plastic shields enclose the sharpest parts of the trocar. Although complications like small bowel perforation, injury of parenchymatous organs, or vascular injury occur in very few cases, they might become life-threatening. We investigate differences of epidemiological, economical, as well as forensic aspects in the use of 'ordinary' and 'safety' trocars, but also the performance of minilaparotomy prior to trocar placement.

Patients and methods: In two different patient groups laparoscopic surgery was performed In the first group (A) (n=1800), ordinary trocars without safety-mechanism were used In group B (n=1200), at least the first used trocar was a 'safety' trocar In the most recent group of 65 patients (group C), a minilaparotomy was performed prior to trocar placement The study design is based on a retrospective analysis

Results: The overall low incidence of trocar-induced complications (0·3 per cent [n=6] group A; 0 2 per cent [n=2] group B; 0 per cent group C). However, both trocar types hold a risk of relevant trocar injury Interestingly, the complication rate of group A and group B did not differ significantly by using the Wilcoxon χ^2-test

Conclusions: The advantages in the use of safety-trocars in our study did not appear as clearly as previously suggested. Possible reason for this result is the failing release of the safety-mechanism in extremely thick abdominal wall or severe peritoneal adhesions The higher the number of patients, the more conclusive and reliable are data concerning the real advantage of safety trocars Although the number of patients with minilaparotomy might be too small to prove statistical significance, the minilaparotomy prior to trocar placement seems to be the safest method to prevent trocar-related complications

Thoracoscopy – a sufficient tool for diagnosis and treatment of lung diseases

J. Kowalewski and M. Dancewicz *The First Surgical Department of the Military Medical Academy in Łódź, Poland, ul. S. Zeromskiego 113, 90-549 Lodz, Poland, E-mail· waml klch@polbox.com*

Aim: The aim of the study was to evaluate the efficiency of thoracoscopy in diagnosis and treatment of lung tumours, management of pulmonary emphysema and treatment of complications after open thoracic operations

Materials and methods: The studied group consisted of 62 patients (42 males and 20 females) who were subjected to 67 thoracoscopic procedures The following operations were performed 34 diagnostic thoracoscopies, 25 cases of pneumoraphie due to spontaneous pneumothorax, 10 cases of lung tumours excision, three cases of closing bronchial stump fistulas

Results: In 31 out of 34 patients (91 2 per cent) thoracoscopy allowed the histological diagnosis of lung lesion to be obtained and appropriate treatment to be introduced In 15 cases one thoracoscopic procedure and in three cases two such procedures were efficient to treat pneumothorax due to pulmonary emphysema (18 out of 25 = 72 per cent) In nine out of 10 cases thoracoscopy was efficient in radical removing of benign lung tumour Using thoracoscopy we managed to close the main bronchial stump fistula after pulmonectomy in two out of three cases There were no intraoperative or postoperative complications connected with these procedures

Conclusions: We consider thoracoscopic technique to be a suitable method for the diagnosis and treatment of pulmonary lesions

Aberrant left hepatic artery in laparoscopic fundoplication

T. Lafullarde, R. Van Hee and T. Gys* *Academic Surgical Centre Stuivenberg, Antwerp, Belgium, *Department of Surgery, A.Z. St. Dimpna, Geel, Belgium*

An aberrant left hepatic artery (AHA) arises from the left gastric artery in 10–30 per cent based on angiographic series or cadaver studies. It may concern an accessory or a solitary branch to the left liver lobe. The location of this AHA is such that it can compromise proper dissection of the hiatus in laparoscopic gastro-oesophageal reflux surgery.

Material and methods: A series of 68 laparoscopic fundoplications is studied in a retrospective manner concerning the presence and management of an AHA. Literature is reviewed.

Results: In 14 of 68 laparoscopic fundoplications (20·6 per cent) an AHA was present and complicated the procedure. It necessitated conversion in two patients, due to impaired vision on the hiatus, and was ligated in another patient which results in a transient rise of liver function tests postoperatively. Due to two dimensional vision in laparoscopic procedures and relatively fixed angle of vision, the AHA, if present, is more impairing proper hiatal dissection than in open procedures. In open esophageal or gastric surgery the occurrence of an AHA is described in approximately 20 per cent of patients and its ligation has led from a transient rise in liver function tests postoperatively to ischemia of the left liver lobe, necessitating partial hepatectomy, and even some deaths.

Conclusions: When performing laparoscopic fundoplication we must be aware of the possible presence of an AHA and, when encountered, effort should be made to preserve it, since injury can give rise to serious morbidity. Lowering of the liver retractor can reduce tension on the aberrant artery and create a greater window for hiatal dissection as well as looping the artery for careful manipulation. If proper dissection can not be insured, conversion is preferable over ligation.

Endoscopic sphinterotomy as an alternative of the operation in patients with high operative risk

R. Markert, J. Klimczak, M. Gryszkiewicz, J. Wasiak and D. Sokołowski *Clinic of General Surgery and Transplantology, 90-153 Łódź, Kopcińskiego 22, Poland*

Dynamic progress of the endoscopic technique allows to remove gallstones from the main bile duct. The purpose of the study is comparison of the patients who were surgically treated on choledochal stones and through endoscopic sphincterotomy.

Between 1989–1995, 236 patients were operated on for choledochal stones. Seventy-one per cent were over the age of 65 years. Diabetes, circular insufficiency, cardiac diseases and obesity were the most common among them. In this group of patients the operative mortality accounted for nine per cent.
